gastrostomy with resection of the stenosed lower end of the esophagus may have to be performed

*Developmental Abnormalities* —These include congenital atresia of the esophagus with tracheo esophageal fistula esophageal webs diverticula congenital short esophagus and paraesophageal hernia

Total regurgitation of food and an aspiration pneumonia in the newborn infant are the cardinal diagnostic points of congential atresia of the esophagus with tracheo esophageal fistula It can be treated with some chance of success if a skilled thoracic surgeon is available

Esophageal webs represent redundant folds of mucous membrane capable of causing obstructive symptoms Identification of the condition is made by esophagoscopy and treatment consists in rupture of the web and subsequent bouginage

Diverticula are of two types pulsion diverticula and those due to external traction The former are typically to be found at the pharyngoesophageal junction (an area inadequately protected by the cricopharyngeal muscle layers) and at the point where the left bronchus crosses the esophagus anteriorly and may cause pressure Pouches may also occur as the result of local injury as from a lye burn Symptoms depend upon the size of the pouch the amount of food stasis that occurs and in the case of a large diverticulum upon the fact that when full it may actually compress the adjacent segment of the gullet with consequent obstruction Localization of symptoms is usually remarkably accurate In the case of those diverticula at the pharyngo-esophageal junction the full pouch may form a mass easily noted by the patient in the supraclavicular region Small diverticula usually are symptomless unless they act as trigger points in disturbing normal motility in overreactive individuals Traction diverticula are lateral outpocketings as the result of an adjacent inflammatory cicatrizing process in the mediastinum They are usually small in size and of little importance except as noted above Diagnosis of diverticula is easily made by *x* ray Mild symptoms can be readily controlled by simple dietary measures When symptoms become prominent and cause severe pain due to local spasm or regurgitation of retained food surgical intervention becomes advisable and proper plastic measures can be carried out by the transthoracic route

Congenital short esophagus is relatively uncommon In this condition the stomach is pulled directly through the esophageal hiatus into the thoracic cavity There is frequently a development of actual gastritis in the herniated portion of the stomach and occasionally of peptic ulcer of the esophagus in the segment just above the cardia with more or less typical ulcer symptoms It will be discussed under inflammatory lesions

Hiatus hernia represents a developmental defect secondary to a large esophageal hiatus Symptoms may be entirely absent

Severe substernal pain secondary to esophageal spasm may at times be sufficient to necessitate the occasional use of narcotics. When encountered, it should suggest the presence of abnormalities, such as esophageal ulcer, diverticulum or hiatus hernia. In the absence of structural changes treatment should be directed toward control of emotional disturbances, regulation of diet, avoidance of rapid eating and restriction in the use of tobacco and alcohol. The use of atropine or similar antispasmodics before the ingestion of food may be very helpful. Immediate relief of pain may be procured by the use of nitroglycerine and occasionally by the sipping of a hot solution of bicarbonate of soda. Functional dysphagia and globus hystericus may occur in emotionally unstable persons of either sex. The most prominent symptom is a fear of choking following the ingestion of either solid or liquid foods. The diagnosis of these nervous manifestations is untenable unless the possibility of more serious organic disease of the esophagus has been ruled out by careful esophagoscopic examination.

Local neurological disease such as bulbar palsy secondary to tabes or any other disease of the central nervous system may produce swallowing difficulties. Similarly, myasthenia gravis may make swallowing difficult or impossible as the result of fatigue of the pharyngeal muscles.

Achalasia of the cardia or so-called cardiospasm presents a different type of clinical picture. This condition is usually encountered in young neurotic individuals. As the term implies, there is failure of relaxation of the lower segment of the esophagus just above the cardia with resulting difficulty in the passage of food and secretions into the stomach. The fundamental cause is not entirely clear. It may be due to degeneration or absence of the ganglion cells in Auerbach's plexus in the terminal segment of the esophagus or theoretically it may be caused by inadequate or vestigial control of this segment by the vagus nerve. In any event there appears to be a functional overstimulation of the cardiac segment by sympathetic stimuli with resulting failure of normal relaxation. A curious and rare condition that is almost indistinguishable from the above condition is associated with hypertrophy of the esophageal musculature just proximal to the cardia with resulting "cardiospasm." In either case gradual dilatation of the esophagus results. Over the years there is an associated local esophagitis secondary to the stasis of food and secretions. This is initially marked by swelling and local congestion and subsequently fibrotic thickening, with permanent constriction of the lumen. X-rays of the esophagus show varying degrees of dilatation and tortuosity, with a smooth, symmetrical fusiform narrowing at the lower end. Esophagoscopy will characteristically show varying degrees of esophagitis in the lowest portion, occasionally with minute superficial erosions. Initial symptoms of achalasia are those of substernal fullness, but as the disease progresses symptoms of obstruction develop with dysphagia and regurgitation of food. The latter characteristically occurs at night and may produce an aspiration pneumonitis. Symptoms are aggravated by emotional tension, hurried eating and the ingestion of bulky or very cold foods. Remissions are frequent in the earlier months or years of the condition. When dysphagia is a prominent symptom it may be accompanied by severe malnutrition. Diagnosis is readily established in most instances by *x*-ray examination of the esophagus. The possibility of esophageal cancer must never be forgotten, and when persistent narrowing has occurred, esophagoscopy with a biopsy from the stenosed area is frequently indicated. Treatment obviously depends upon the stage of the disease. In the early stages treatment consists in the proper handling of emotional difficulties and regulation of diet and eating habits. Bulky, irritating or extremely cold foods should be avoided, as should alcohol and tobacco. The use of nitrites before the ingestion of food is frequently of great help. In the later stages of the disease careful bouginage at regular periods may alleviate the symptoms and permit an adequate food intake. It should only be carried out by an experienced endoscopist. If attempts to relieve symptoms by the passage of bougies or of dilating bags is not successful, then resort to surgery may be necessary. In this event an esophago-

with an acute inflammatory process involving the interior and exterior surfaces Such traumatic accidents if not immediately fatal may subsequently produce cicatricial strictures with varying degrees of obstruction The acute reactions to trauma may include mediastinitis with fever leukocytosis *etc* Treatment here consists in the careful feeding of bland foods provided emergency surgery is not indicated and the use of antibiotics Residual strictures require the use of guided bougies and rarely resection of stenosed areas and anastomotic surgery

Specific granulomatous diseases such as syphilis and tuberculosis rarely cause local ulceration, cicatrization and stenosis with accompanying obstructive symptoms Scleroderma may be the cause of multiple irregular constricting lesions in the esophagus The diagnosis in each instance is made by recognition of other manifestations of the disease in question

Peptic ulcer of the esophagus may occur It is likely to appear in the congenital short esophagus possibly because of the easy regurgitation of gastric juice that occurs in this condition The ulcer is found near the cardia and produces symptoms of two types one is characteristic of ulcer in general—pain after eating relieved by food or antacid the other is essentially esophageal and is due to the associated spasm which may in itself cause severe intractable pain and dysphagia With recurrent attacks, stenosis of the esophagus typically develops with frank obstruction Diagnosis is made by radioscopic examination or by direct endoscopy If routine measures employed in the treatment of peptic ulcer are not effective the disease may progress until sufficient obstruction exists to warrant resection and esophagogastrostomy In general it may be said that the condition is extraordinarily difficult to handle Complications are those of peptic ulcer elsewhere It should be mentioned that peptic ulceration of the esophagus is not infrequently associated with gastric or duodenal ulceration

Acute esophagitis not only may be associated with trauma from various causes but may also accompany an acute infectious disease such as diphtheria, smallpox typhoid or thrush It is of course a serious complication Chronic esophagitis may be the commonest disease of the esophagus In the majority of instances it is directly related to other diseases of the digestive tract especially to those in which vomiting or regurgitation of acid gastric secretions is of frequent occurrence Many cases have been noted in association with hiatus hernia esophageal ulcer, duodenal ulcer and in recent years, esophagogastrostomy It eventually produces shortening and stricture at or near the esophagogastric junction causing dysphagia and regurgitation usually without nausea or real vomiting Heartburn is common and inability to belch is frequently noted Diagnosis is by *x* ray examination and esophagoscopy Once the possibility of malignancy in the stricture is eliminated successful therapy usually can be obtained by careful dilatation with a string guided bougie If dysphagia is unrelieved by this means resection of the stricture and esophagogastrostomy is indicated

*Degenerative Disease* is associated with atrophic changes in the esophageal mucosa and is encountered in such conditions as pellagra the Plummer-Vinson syndrome pernicious anemia and other similar deficiency states The substernal burning encountered in pellagra responds readily to niacin therapy Adequate iron therapy may relieve esophageal symptoms encountered in the Plummer Vinson syndrome whereas the use of liver or vitamin $B_{1}$ will readily improve the occasional esophageal symptoms encountered in pernicious anemia

*Neoplastic Disease* of the esophagus is most frequently carcinoma Other malignant or benign tumors occur but are numerically of minor importance The majority of esophageal cancers involve the lower and mid portions and are either squamous-cell (esophageal) or adenocarcinomatous (gastric) in character Symptoms are essentially those of an obstructing lesion Early in the course of the disease substernal pain may be present but as a rule difficulty in swallowing loss of appetite and malnutrition are the characteristic symptoms with later regurgitation excessive thirst and constipation of marked degree Bleeding usually of

even when the herniation of the stomach through the esophageal hiatus is readily apparent by *x*-ray examination When symptoms are present they are characterized by high epigastric distress, probably secondary to localized gastritis in the herniated portion of the stomach, or by substernal distress, dysphagia or regurgitation, particularly in the recumbent position, and severe heartburn In patients who have symptoms from a hiatus hernia, anemia secondary to moderate bleeding is not uncommon and gross hematemesis may occur Symptoms are usually not noted before the age of 40 At times, distress associated with hiatus hernia is distinguished with difficulty from symptoms due to coronary heart disease inasmuch as the pain may radiate to one or both shoulders and down the arm Like the pain of angina pectoris the symptoms may be aggravated by emotional tension and overeating It is usually not related to exertion however, and is made worse rather than relieved by the ingestion of alcohol The diagnosis by roentgenologic examination is easy if symptoms are suspected It should be noted that diverticula of the colon duodenum, or small intestine are frequently encountered in association with hiatus hernia It should also be noted that, at times diagnostic difficulties arise because of coexisting coronary heart disease or the presence of cholelithiasis Treatment comprises the use of frequent small feedings of non irritating food, the use of antispasmodics and antacids, and simple but intelligent psychotherapy If symptoms become intractable or if major bleeding occurs, transthoracic surgical repair of the hernia is necessary and will usually be accompanied by an excellent result

*Neighborhood Disease* is associated with mediastinal tumors aneurysm of the aorta metastatic disease causing enlargement of mediastinal glands extreme cardiac enlargement or pericardial effusion (rare) and occasionally inflammatory disease of the diaphragmatic pleura which may cause esophageal compression or irritation The cause of symptoms is usually apparent on radioscopic examination Therapy should be directed toward the primary disease

*Inflammatory Disease or Traumatic Disease* involving the esophagus usually is intraluminal Perforation of the esophagus by instrumentation ingested foreign bodies or caustics or rupture of the esophagus by excessive vomiting may be associated

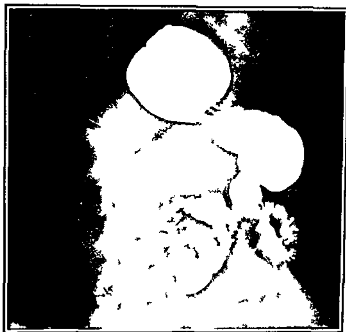

FIG 197 —Hiatus hernia About one third of stomach above curve of diaphragm

and such a diagnostic procedure is entirely justified if other methods fail to demonstrate the source of major upper gastrointestinal bleeding. Therapeutic measures will be discussed in a later section.

## DISEASES OF THE STOMACH

Gastric disturbances may be associated with abnormalities of motor or secretory function, developmental abnormalities, new growths, and with focal or diffuse inflammatory processes. Symptoms arising from the stomach are almost always referred to the epigastrium and may be described by such terms as fullness, distention, gas, heartburn, gnawing or burning pain. In addition, more general symptoms may be anorexia, nausea and vomiting. None of these symptoms is specific for any particular disease, but in general it can be said that periodic gnawing pain suggests local ulceration, that a steady burning or aching pain suggests a more diffuse inflammatory process such as gastritis, and that nausea and vomiting imply the probability either of a diffuse acute inflammatory process or of partial obstruction. In almost every instance symptoms are related to the intake of food, which may relieve or may aggravate the discomfort. Diagnosis of disease of the stomach depends primarily on a good history, which should include a careful analysis of eating habits, dietary adequacy, and the use of alcohol, tobacco, coffee, tea, and certain irritating drugs such as the salicylates and the newer antibiotics. Physical examination may reveal local distention, a palpable mass, or local tenderness as confirmatory evidence of gastric disease. Further definition of the type and location of gastric disease can be obtained by adequate roentgenologic examination or by gastroscopy. Gastric analysis rarely provides diagnostic material, at the best it gives evidence of excessive gastric secretion or true achlorhydria. In cases of obstruction it aids in measuring the degree of retention or of gastric emptying. Careful cytological studies of gastric residues properly obtained and stained with the Papanicolaou technique may prove the presence of malignant cells, but this method can only be utilized where the services of a highly trained technician are available.

Motor Disturbances.—*Gastric atony* may occur as an acute phenomenon resulting in marked dilatation of the stomach. It is accompanied by weakness, epigastric fullness, regurgitation, nausea and vomiting. There is usually striking electrolyte loss with dehydration if the condition persists for any period of time. Pain is not remarkable. The vomitus is large in amount and usually bile-stained, or it may be black in color; in the latter case it represents old changed blood. Examination reveals a rapid thready pulse, frequently with an accompanying sharp rise in temperature and respirations, and in severe cases with evidence of shock or collapse. The abdomen is soft, distended, and there may be a succussion splash in the epigastrium.

The condition usually occurs shortly after major operation or after obstetrical delivery. It may be encountered in severe diabetic coma. If not recognized and treated energetically, it may result in coma and death. Treatment consists in gastric lavage and parenteral replacement of fluids and electrolytes. Aspiration frequently yields as much as from 3,000 to 4,000 cc. At times several aspirations may be necessary in order to restore tone to the gastric musculature. Following such an occurrence, feeding must be limited to very small amounts at a time. Postoperative gastric suction serves to prevent the development of acute dilatation of the stomach in most instances.

Atony of the stomach may occur in general debilitating diseases. Under such conditions its onset is very gradual, and a diagnosis is made only after careful observation and demonstration of gastric stasis without evidence of organic obstruction. It may also occur as a result of gradually increasing pyloric obstruction due to stenosing lesions. Under these circumstances it will almost invariably be associated with vomiting of increasing amounts of food. X-ray examination will show a dilated atonic stomach which should be treated by repeated aspirations or constant suction plus parenteral replacement of fluids and electrolytes. Ultimately, the pyloric obstruction must be treated surgically. The large, sagging stom

a minor degree may occur. An early diagnosis must depend upon an awareness of the significance of substernal distress in relation to the intake of food and anorexia. Roentgen ray studies, especially in older patients, are always warranted. It should be noted that in certain instances, obstructive symptoms associated with an obvious esophageal constriction may have been present for a long time. Barium studies may show an irregular lesion or occasionally a symmetrical narrowing. Esophagoscopy should be performed for the purpose of obtaining biopsy material from the stenosed area. The esophagoscopist should be prepared *to dilate* the constriction by means of a guided bougie in order to obtain an adequate biopsy from the center *of the* stricture.

Radical resection is dangerous and cure is infrequent especially in the later decades but skilful surgery may produce palliation from the distressing dysphagia *for two or* more years in a reasonable number of patients. In inoperable cases, intensive radiation at times produces extraordinary temporary results, and complete relief of dysphagia can frequently be obtained by careful dilatation of the constricted area by guided bougies.

The other benign or malignant tumors of the esophagus are less common than carcinoma and involve the same diagnostic and therapeutic considerations.

Fig 198.—*Cancer of the esophagus. Note irregular asymmetrical narrowing below dilatation*

*Esophageal Varices* are a common manifestation of any condition causing portal hypertension. They are entirely asymptomatic until gross hemorrhage occurs. Demonstration of esophageal varices can be provided by careful roentgen ray studies. Occasionally the presence of esophageal varices may be suspected but *x* ray demonstration may be difficult or impossible. Under such circumstances they may be readily recognized by careful es... py,

mal functioning Demonstration of gastroptosis or visceroptosis in a patient with symptomatic complaints should direct attention to that type of therapy which is chiefly concerned with the regulation of living habits and emotional difficulties

*Diverticula* of the stomach are either congenital or secondary to pulsion or traction They are relatively uncommon and they are usually seen in the region of the cardia Diagnosis is practically always an accidental one and is made in the course of a routine *x* ray examination Symptoms from gastric diverticula are rare but local inflammation may occur with epigastric discomfort or pain in relation to the intake of food In those instances in which a gastric diverticulum is secondary to traction from neighborhood disease relief of symptoms can be obtained only by treating the primary condition In rare instances in which the diverticulum is fairly large with accompanying stasis of food surgical excision or invagination of the diverticulum may be required

At this point it should be noted that diverticula may frequently occur in the duodenum and in the remainder of the small intestine Duodenal diverticula are fairly common and are usually found by accident in the course of a routine roentgen ray examination They rarely cause symptoms Occasionally they become the seat of an inflammatory process and cause epigastric distress and fullness Under these circumstances symptoms as a rule occur after a big meal and more particularly during the night The symptoms probably are due to faulty emptying of the diverticula and this can be demonstrated by giving a swallow of barium at bedtime and then *x* raying the patient while still in the horizontal position the first thing in the morning If there is marked stasis of barium then one may assume that symptoms are associated with the diverticulum and a program of small frequent feedings with particular reference to the evening meal may be of real help Diverticula in the first portion of the duodenum are of the traction variety and more frequently associated with duodenal ulcer Jejunal and ileal diverticula are usually asymptomatic but occasionally they are very numerous and may cause a sprue like picture with steatorrhea macrocytic anemia and general malnutrition

*Hiatus hernia* has been discussed in a previous section It may occur in association with the protrusion of other abdominal viscera through the diaphragm but it is more commonly encountered as the so-called paraesophageal hernia Where symptoms warrant surgical intervention operative repair of the hernia can best be accomplished by the transthoracic route and in skilled hands this operation has a very low mortality rate, probably under 2 per cent The herniation usually is the result of a developmental abnormality in the diaphragm but it may be the result of trauma to the diaphragm from a severe blow In the latter case surgical repair is usually indicated

*Hypertrophic stenosis* of the pylorus consists in obstructive narrowing secondary to hypertrophy of the pyloric muscle It most frequently occurs in newborn infants It may gradually develop in adults and under these circumstances, may be associated with an ulcerative process in the vicinity of the pyloric end of the stomach Symptoms in infants occur most frequently within a few weeks of birth but they may be noted as late as several months after delivery The condition occurs three or four times more frequently in male children than in female children In infants the pyloric region is found to consist of a mass of thickened muscular tissue that is extremely hard and involves an area 2–3 cm in length There is no evidence of inflammation The symptoms which are characteristic are persistent projectile vomiting loss of weight constipation and dehydration Physical examination typically reveals a distended globular stomach with easily visible peristaltic waves proceeding from left to right after the intake of food Occasionally a small rounded tumor may be palpated in the region of the pylorus if the child is sufficiently relaxed Easy confirmation of the diagnosis can be obtained by a barium swallow Initial treatment consists in sedation with small subcutaneous doses of sodium phenobarbital with or without the addition of very minute doses of atropine Small frequent feedings of breast milk or prepared milk with a very fine curd should be used If such conserva

ach seen in visceroptotic individuals is not an example of gastric atony and very rarely gives rise to symptoms

*Local spasm* of the stomach may occasionally be encountered in the presence of focal ulcerating lesions Segmental spasm may also be seen in conditions, such as tabes dorsalis and other similar diseases of the spinal cord, and may occasionally be encountered in lead poisoning Where spasm is intense, it is associated with the production of pain

*Nervous vomiting* is indirectly an example of disturbed gastric motility secondary to profound psychiatric difficulties It is characterized by frequent effortless vomiting of portions of meals, without nausea and without loss of weight Although the patient complains constantly of vomiting, careful history almost always brings out a story of emotional difficulties that may be in the nature of true hysteria or of other typical neurotic manifestations Careful *x* ray examination is often indicated in order to rule out organic disease Once the identity of the problem is apparent, psychotherapy offers the only source of relief It is not always effective

SECRETORY DISTURBANCES —Variations in the volume of gastric secretion or in the concentration of acid or pepsin cover a broad range and are frequently encountered in any group of normal individuals An increase or a decrease in gastric secretory activity can be readily produced by emotional factors as shown by Wolf and Wolff and by numerous other investigators Fear may depress secretory activity to a very low level, and conversely anger and frustration may increase the volume and concentration of gastric secretions So-called hyperacidity and hypo acidity have little meaning and certainly have little or no relationship to the production of symptoms In general, it can be said that variations in secretory activity are not to be correlated with specific symptoms or diseases Two exceptions are chronic peptic ulcer and pernicious anemia The former is associated with hypersecretion and is practically never encountered in a continuing absence of gastric juice whereas patients with pernicious anemia rarely, if ever, show evidence of gastric acidity Total achlorhydria, with failure to respond to histamine stimulation, may occur in perfectly normal individuals The incidence of such a finding increases progressively with increase in age It may also be encountered in a high percentage of cases of gastric carcinoma and as noted above, in patients with pernicious anemia or combined degeneration of the spinal cord

*Achlorhydria* may occur as a result of chronic gastritis, with an ultimate, irreversible change in the gastric mucosa This change is an atrophic one and may also be encountered in certain deficiency diseases, in which it is more properly classified as gastric atrophy than as atrophic gastritis In the absence of free hydrochloric acid in the stomach, more rapid emptying of the organ obtains and it is possible that, occasionally so-called gastrogenic diarrhea may result from this secretory disturbance The proof of such an entity is not always readily obtained, and the diagnosis should not be made until other causes of diarrhea are excluded In the absence of other causes, seemingly intractable diarrhea usually in older people may be relieved by the use of adequate doses of dilute hydrochloric acid (U S P ) or glutamic acid hydrochloride taken with meals The diagnosis is never justifiable unless a demonstrated achlorhydria has been shown to be present in the absence of any other morbid condition of the alimentary tract

DEVELOPMENTAL ABNORMALITIES — *Visceroptosis* —For the most part developmental abnormalities are not productive of symptoms and do not require treatment Mention should be made of the term *gastroptosis* in relation to so called visceroptosis or Glenard s disease In this condition ptosis of the stomach occurs in association with a sagging position of most of the other abdominal viscera In all probability this condition should not be credited as being the cause of symptoms although much attention has been paid to it in the past Individuals with this condition are almost invariably of an asthenic build and symptoms are usually manifestations of an underlying neurasthenia The position of the stomach or for that matter of other abdominal organs rarely if ever seriously interferes with nor

widespread necrosis of the gastric mucosa if sufficient material passes the esophagus and still remains active when it reaches the stomach. An especially severe type of acute gastritis is that classified as phlegmonous gastritis. This type is due to a pyogenic infection, usually streptococcal in origin, which begins as a localized cellulitis and may develop into a circumscribed abscess or a diffuse phlegmon.

The symptomatology of acute gastritis ranges from that of nausea and vomiting with mild epigastric discomfort to extremely diffuse epigastric pain and local tenderness with severe vomiting, fever, dehydration and a septic course. In all but the most severe cases a diagnosis will be made on the basis of a history of marked dietary indiscretion, the ingestion of some corrosive substance or intercurrent infection immediately preceding the onset of symptoms. X-ray examination or gastroscopy is in most instances entirely unnecessary. Treatment consists simply in the administration of frequent small feedings of very bland foods, moderate sedation, and the use of antacids. If lye or some other corrosive substance has been swallowed, instrumentation of any sort should be avoided and the patient should be given only soothing liquids such as milk, egg albumen, thin jellies and the like. Once the acute symptoms have subsided, *x*-ray examination of the esophagus and stomach should be performed to determine the amount of injury that has resulted. The patient's course should be followed with care, inasmuch as healing is associated nearly always with cicatricial stenosis and frequently with obstruction either in the esophagus or in the stomach or both. If this occurs, careful dilatation by guided bougies or plastic surgery is indicated. Phlegmonous gastritis is rarely diagnosed preoperatively, but the intensity of the epigastric symptoms, the degree of local tenderness and the septic temperature may give an indication. The use of antibiotics is indicated and, if necessary, surgical intervention with drainage or resection.

*Chronic gastritis* has been classified in various manners and by the use of various descriptive terms. With the advance in our knowledge of this subject following the introduction by Schindler of the flexible gastroscope, a precise diagnosis is now possible, and in all probability the simplest classification is the best. That suggested by Benedict would seem to have particular merit because of its simplicity and because it corresponds adequately to the findings of the pathologist. This classification divides gastritis into three categories—superficial, hypertrophic and atrophic. The term *gastric atrophy* should be used to differentiate atrophy of the stomach secondary to deficiency disease from that due to a local or diffuse inflammatory process. The former is more or less completely reversible with adequate replacement therapy. Superficial gastritis may be found as a separate entity or combined with atrophic gastritis. Patchy areas of gastric atrophy may also be noted in combination with other forms of gastritis.

The *diagnosis* of gastritis may be suggested by the symptomatology presented by a given patient but can be definitely determined only by adequate gastroscopic observation. In many instances a diagnosis of hypertrophic gastritis can be suggested by the radiologist on the basis of thick mucosal folds and an increased secretion of mucus. Such a diagnosis is not conclusive, however, and striking instances have occurred in which an *x*-ray diagnosis of hypertrophic gastritis has been shown to be erroneous because of obvious gastroscopic findings of almost complete atrophy of the gastric mucosa. The gastroscopic picture in acute superficial gastritis is that of reddening, edema, and adherent secretions. Erosions are not infrequently seen, and areas of submucosal hemorrhage are common. The red edematous mucosa is easily traumatized with subsequent bleeding. Chronic hypertrophic gastritis characteristically presents a verrucous appearance of the mucosa, with obvious hypertrophy of the gastric folds. At times the warty elevations are so large as to suggest tumor formation, and differentiation between severe hypertrophic gastritis and an infiltrating tumor may be impossible. Under such conditions biopsy of the gastric mucosa through the operating gastroscope frequently provides diagnostic material. Atrophic gastritis and gastric atrophy present an endoscopic appearance of a very thin, smooth, pale-gray

tive measures fail to control symptoms and to permit adequate food intake then recourse must be had to surgical intervention This is accomplished by means of the so called Rammstedt operation a procedure *which divides the pyloric muscle longitudinally down to the mucosa* The operation is highly successful in competent hands if it is performed without undue delay

In adults, pyloric hypertrophy may represent the persistence of the congenital condition described above or may be associated with inflammatory disease such as gastric ulcer or gastritis In the absence of inflammatory disease the condition may be relatively asymptomatic or may be marked by periodic episodes of moderate nausea and vomiting which may increase in severity as time goes on Unless there is an associated lesion pain is not present The exact diagnosis of this condition is adults is difficult A preceding story of numerous episodes of periodic vomiting without pain may lead to the suspicion that the condition exists Roentgenologic studies may suggest the disease because of the abnormal width of the pylorus and dilatation of the stomach It may be impossible however, to differentiate this condition from a scirrhous type of carcinoma involving the pyloric end of the antrum Confirmatory evidence may be obtained occasionally by gastroscopic examination particularly if the pyloric end of the stomach is visible through the gastroscope and it is possible to obtain biospy material In the presence of gastric ulcer as will be subsequently discussed the first consideration is to reach the decision that the ulcerating lesion is benign *If any doubt exists or* if antral cancer can be demonstrated radical surgery is indicated with adequate gastric resection If the condition is associated with a benign gastric ulcer recurrences are to be expected in most instances and medical treatment over any period of time is relatively unsuccessful If pyloric hypertrophy alone is present simple pyloroplasty is indicated in the presence of persistent symptoms

Foreign Bodies —Foreign bodies to be found in the *stomach* range from pins tacks and nails to objects as large as knives, forks and spoons In most instances the foreign body has been swallowed by accident but occasionally, swallowing such an object is the act of a mentally unbalanced individual Most of the smaller objects are passed through the stomach and emerge in the stool without causing harm Occasionally however, sharply pointed objects may penetrate the wall of the stomach causing local bleeding or actual perforation with subsequent peritonitis When a history can be obtained of an accidentally swallowed foreign body the patient should be referred to a competent esophagoscopist at once and localization of the object should be obtained by fluoroscopy or *x* ray examination If a satisfactory passage of the object through the stomach into the alimentary canal does not occur then removal should be performed either by the endoscopist with special instrumentation or by gastrotomy

The most interesting foreign body is that known as a *bezoar* a large concretion which may be composed of hair plant fibers shellac or other substances The symptoms from such a concretion depend upon its size and the irritation that it may cause in the stomach itself Epigastric heaviness fullness pain or periodic vomiting attacks may occur Organic disease such as ulcer or neoplasm may frequently be mimicked by the presence of a bezoar in the stomach The diagnosis can be established by roentgenologic examination because of the finding of a large filling defect which is freely movable and ordinarily located in the antrum Gastroscopic examination may demonstrate the nature of the mass Treatment consists in gastrotomy Complications of this condition will be those of either ulceration or obstruction

Inflammatory Diseases of the Stomach —*Gastritis* is undoubtedly the commonest disease of the stomach It frequently appears as an *acute* manifestation due to mechanical irritation by coarse foods overeating or overindulgence in alcohol or it may be produced by specific infectious diseases notably diphtheria scarlet fever and measles in children and influenza in adults It may also result from irritating drugs such as aspirin nicotine caffeine and the like The corrosive effect of such substances as lye and cresol which have been swallowed by accident or with suicidal intent may produce

widespread necrosis of the gastric mucosa if sufficient material passes the esophagus and still remains active when it reaches the stomach. An especially severe type of acute gastritis is that classified as phlegmonous gastritis. This type is due to a pyogenic infection, usually streptococcal in origin, which begins as a localized cellulitis and may develop into a circumscribed abscess or a diffuse phlegmon.

The symptomatology of acute gastritis ranges from that of nausea and vomiting with mild epigastric discomfort to extremely diffuse epigastric pain and local tenderness with severe vomiting, fever, dehydration and a septic course. In all but the most severe cases a diagnosis will be made on the basis of a history of marked dietary indiscretion, the ingestion of some corrosive substance or intercurrent infection immediately preceding the onset of symptoms. X-ray examination or gastroscopy is in most instances entirely unnecessary. Treatment consists simply in the administration of frequent small feedings of very bland foods, moderate sedation and the use of antacids. If lye or some other corrosive substance has been swallowed, instrumentation of any sort should be avoided and the patient should be given only soothing liquids such as milk, egg albumen, thin jellies and the like. Once the acute symptoms have subsided, x-ray examination of the esophagus and stomach should be performed to determine the amount of injury that has resulted. The patient's course should be followed with care, inasmuch as healing is associated nearly always with cicatricial stenosis and frequently with obstruction either in the esophagus or in the stomach or both. If this occurs, careful dilatation by guided bougies or plastic surgery is indicated. Phlegmonous gastritis is rarely diagnosed preoperatively, but the intensity of the epigastric symptoms, the degree of local tenderness and the septic temperature may give an indication. The use of antibiotics is indicated and, if necessary, surgical intervention with drainage or resection.

*Chronic gastritis* has been classified in various manners and by the use of various descriptive terms. With the advance in our knowledge of this subject following the introduction by Schindler of the flexible gastroscope, a precise diagnosis is now possible, and in all probability the simplest classification is the best. That suggested by Benedict would seem to have particular merit because of its simplicity and because it corresponds adequately to the findings of the pathologist. This classification divides gastritis into three categories—superficial, hypertrophic and atrophic. The term *gastric atrophy* should be used to differentiate atrophy of the stomach secondary to deficiency disease from that due to a local or diffuse inflammatory process. The former is more or less completely reversible with adequate replacement therapy. Superficial gastritis may be found as a separate entity or combined with atrophic gastritis. Patchy areas of gastric atrophy may also be noted in combination with other forms of gastritis.

The *diagnosis* of gastritis may be suggested by the symptomatology presented by a given patient but can be definitely determined only by adequate gastroscopic observation. In many instances a diagnosis of hypertrophic gastritis can be suggested by the radiologist on the basis of thick mucosal folds and an increased secretion of mucus. Such a diagnosis is not conclusive, however, and striking instances have occurred in which an x-ray diagnosis of hypertrophic gastritis has been shown to be erroneous because of obvious gastroscopic findings of almost complete atrophy of the gastric mucosa. The gastroscopic picture in acute superficial gastritis is that of reddening, edema and adherent secretions. Erosions are not infrequently seen, and areas of submucosal hemorrhage are common. The red, edematous mucosa is easily traumatized with subsequent bleeding. Chronic hypertrophic gastritis characteristically presents a verrucous appearance of the mucosa with obvious hypertrophy of the gastric folds. At times the warty elevations are so large as to suggest tumor formation and differentiation between severe hypertrophic gastritis and an infiltrating tumor may be impossible. Under such conditions, biopsy of the gastric mucosa through the operating gastroscope frequently provides diagnostic material. Atrophic gastritis and gastric atrophy present an endoscopic appearance of a very thin, smooth, pale gray

mucosa through which blood vessels are easily visible Gastric rugæ are absent Atrophy may be complete or it may be patchy In complete atrophy there is histamine achlorhydria

The *symptomatology* of chronic gastritis is not characteristic Epigastric distress nausea, vomiting hemorrhage, loss of weight, etc may be encountered In many instances aside from nutritional disturbances patients complain of few or no symptoms referable to the stomach At times, the history is that of a rather atypical ulcer or gastric cancer At other times, epigastric discomfort and accompanying symptoms may seem to be entirely independent of food and unrelieved by antacids It should be pointed out that, frequently superficial gastritis and at times hypertrophic gastritis are seen in association with peptic ulcer of the stomach or duodenum

Once the diagnosis of gastritis is established, *treatment* may be instituted on the basis of a general program of careful regulation of eating habits with the institution of small regular feedings of bland food eaten slowly and on time Excessive smoking should be avoided, as should the use of alcohol tea and coffee Simple medication such as aluminum hydroxide antacid preparations mild sedation with the barbiturates, and antispasmodics, is frequently of assistance in controlling symptoms In cases in which there is complete gastric atrophy and histamine achlorhydria it is important to rule out such conditions as primary pernicious anemia and (occasionally) nontropical sprue Infrequently patients with gastric atrophy are encountered who do not have either of the above conditions but whose symptoms are those of anorexia loss of weight, vague epigastric distress and moderate anemia unaccompanied by evidences of bleeding These patients respond in a rather dramatic manner to prolonged therapy with liver extract and the gradual administration of a thoroughly adequate diet It has been shown that regeneration of the mucosa may occur under such therapy, as may occasionally be the case in pernicious anemia although gastric secretory changes are seldom if ever, restored, to normal

Special mention should be made of those who present themselves with a story of acute massive gastric hemorrhage with few if any other symptoms In such cases, the obvious duty of the physician is to rule out structural disease, such as peptic ulcer, cancer esophageal varices, and hiatus hernia as the source of bleeding Once this has been done careful gastroscopy is indicated and may provide the necessary explanation and diagnosis Not a few such cases may bleed massively, even to shock levels, solely on the basis of severe superficial gastritis with extreme hyperemia and numerous erosions The cause of such a condition is usually obscure, but, occasionally, a careful history will reveal the excessive use of alcohol or the chewing of such substances as snuff or tobacco with constant swallowing of the irritating material On occasion the continued use of aspirin may produce a similar picture When such a history can be obtained, careful dietary regulation and the elimination of the irritating substance may produce satisfactory regression of the gastric irritation and obviate further serious bleeding Inasmuch as patients may occasionally have a fatal hemorrhage as a result of gastritis of this degree, it is necessary to stress the importance of adequate gastroscopic examination if *x* ray studies are inconclusive or negative It may be mentioned that, occasionally, carefully planned medical regulation fails to control the situation and to prevent repeated episodes of bleeding In these rather rare instances subtotal gastrectomy may be necessary in order to obtain eventual control of dangerous hemorrhage

Finally a note of warning should be given as to the validity of the gastroscopic diagnosis of mild gastritis in the hands of inexperienced gastroscopists Temporary hyperemia hypersecretion, and irritability of the gastric mucosa can and frequently do occur as the result of nervous tension or emotional disturbances This was originally noted by Beaumont and has been brilliantly confirmed by Wolf and Wolff Erroneous diagnoses based on superficial transitory changes in the gastric mucosa are still too common and form the basis of unnecessary and often unwise therapeutic programs without benefit to the patient

Specific Inflammation of the Stomach—This type of inflammation may be due to a granulomatous process secondary to syphilis tuberculosis or such rare conditions as actinomycosis and other rare fungus infections

*Syphilis* may occur as a solitary gumma or as numerous gummatous lesions It may also be present as a diffuse nodular infiltrating process or as chronic fibrosis Symptoms are not sufficiently characteristic to suggest the diagnosis but most frequently simulate peptic ulcer or carcinoma with epigastric distress and marked loss of weight Hemorrhages rarely occur The diagnosis is essentially one of exclusion inasmuch as syphilis may occur coincidentally with peptic ulcer or cancer The radiological findings are not diagnostic but may simulate benign gastric ulcer carcinoma of the pylorus and antrum or diffuse scirrhous carcinoma (leather bottle stomach) Achlorhydria may be present and when found in the presence of an ulcerated lesion and positive serology, it should direct attention to the possibility of syphilis or cancer rather than to that of benign peptic ulcer Gastroscopic examination will readily demonstrate lesions of syphilis in the stomach but will not give a definitive answer In general it can be said that gastric syphilis should be given consideration in all cases in which patients have positive serological tests and demonstrable gastric lesions One added point is that except for symptoms of obstruction most gastric syphilis causes symptoms that appear to be of minor severity in relation to the lesion that has been demonstrated

*Treatment*—Where gastric syphilis is suspected routine antiluetic therapy should be instituted Failure to respond to such treatment should lead to the conclusion that the suspected lesion is probably carcinomatous

*Tuberculosis* of the stomach is usually a manifestation of late or terminal pulmonary tuberculosis In all but a few instances gastric tuberculosis is manifested by the presence of ulcerating lesions although an infiltrative type is recognized Symptomatically there is no characteristic clinical picture and a positive diagnosis can be made neither by *x* ray nor by gastroscopy The actual demonstration of tubercle bacilli in the lesions by direct biopsy is the only means of final identification In most instances treatment is symptomatic, but occasionally the general condition of the patient may warrant surgical intervention with local gastric resection

## PEPTIC ULCER

Although the diagnostic and therapeutic approach to the problem of gastric ulcer differs radically from that involved in peptic ulceration of the duodenum it will be convenient to discuss in general the problem of peptic ulcer involving either segment of the digestive tract As the term is clinically used peptic ulcer represents a chronic recurrent circumscribed ulceration of the gastric or duodenal mucosa To date it represents an essentially incurable condition The exact incidence of peptic ulcer is not known but autopsy evidence suggests that it may occur in 10 per cent of all people There is no particular racial predominance but it is four times more frequent in men than in women As a clinical entity it is much more frequently encountered in the duodenum than in the stomach but on the basis of autopsy statistics gastric lesions are more frequent than duodenal The malady may occur at any age from infancy into the late decades it is most common between the ages of twenty and thirty Although the typical ulcer patient is described as a slender asthenic individual it is not at all uncommon to encounter peptic ulcers in stocky somewhat overweight individuals As suggested above most peptic ulcers occur in the stomach or duodenum They may also occur at the cardiac end of the esophagus in the small bowel near the stoma of a gastroenterostomy or opposite the mouth of a Meckel s diverticulum In the stomach the vast majority of benign ulcers occur along the lesser curvature In the duodenum they are most frequently encountered in the first portion, the duodenal bulb Benign gastric ulcers may occur near the cardia along the greater curvature and not infrequently in the prepyloric region or at the pylorus Although usually single multiple ulcers are not uncommon They may occur concomitantly in the stomach or duodenum

or as so-called 'kissing' ulcers on the anterior and posterior walls of the duodenum. The actual size of the ulcerated area varies tremendously in diameter and depth. It always involves the muscularis mucosae and may *penetrate through the deeper layers* producing a complete perforation. The border of the ulcer is sharp, the floor of the ulcer is clean, and the surrounding mucosa may be normal or may show evidence of gastritis. Benign peptic ulcer is rarely seen in the presence of cancer of the stomach, but the presence of a benign ulcer either in the duodenum or in the stomach does not preclude the possibility of an independent malignant lesion. Peptic ulcer may occur in association with the development of brain lesions or following operation on them. No specific center in the brain seems to be particularly conducive to such an occurrence. During pregnancy, gastric or duodenal ulcer is rarely active.

*Etiology*.—The etiology of peptic ulcer is not known. Undoubtedly, acute ulceration of the stomach or duodenum may occur as the result of *local trauma* from the ingestion of irritating foreign bodies, or it may be associated with *severe burns*, in which case the lesion is known as a Curling's ulcer. Such an ulceration may be complicated by acute perforation or hemorrhage and sometimes may result in a chronic peptic ulcer. *Arterial infarction* or thrombosis may result *in local ulceration but as a rule the collateral* circulation is so adequate that this cause should not be overemphasized. With these exceptions, no satisfactory theory has been presented to date which adequately explains the causation of this common disease.

Fig 199.—Benign gastric ulcer. Note small rounded projection of ulcer crater in mid lesser curvature.

*Gastric hypersecretion* with an increased volume of gastric juice and an increase in gastric acidity is the usual finding in patients with peptic ulcer. In animals, peptic ulceration has been produced by the subcutaneous *injection of histamine and beeswax* with resulting overstimulation of gastric secretion for long periods of time. Various other animal experiments contribute definite evidence as to the importance of the lack of adequate neutralization of gastric digestive juice in the production of peptic ulceration. In human beings, however, proof is still lacking that increased secretion

alone as the cause of the disease. The nearest analogy is the occurrence of stomal ulcers following gastroenterostomy at a point in the mucosa of the jejunum where unneutralized gastric digestive juice is normally not present. Furthermore, it is an interesting fact that a subtotal gastrectomy which fails to remove the pyloric antrum is almost always followed by a stomal or jejunal ulcer, suggesting that the stimulus to excessive secretion was not adequately removed by the original operative procedure. Removal of the remaining antral segment almost invariably controls the situation at once.

*Neurogenic Concept.*—Cushing and others have called attention to the incidence of peptic ulcer in association with brain tumors and surgery for such conditions. The work of Wolf and Wolff has demonstrated the important role of emotional factors in relation to gastric secretory activity, and ulceration of the stomach has been produced by them as a result of slight trauma to the gastric mucosa and excessive nervous stimulation. The neurogenic concept of ulcer causation is indeed a fruitful source for careful consideration, but it must be admitted that this theory, too, fails to explain the etiology of the disease with entire satisfaction.

*Hormonal disturbances* have likewise been considered as an important, if not the most important, factor in the initiation of peptic ulceration. The fact that pregnancy seems to prevent the recurrence of duodenal or gastric ulcer in women is one of the bits of suggestive evidence leading to this type of investigation. Lack of protective mucus in the gastric secretion has also been proposed as an explanation for the occurrence of peptic ulceration.

Suffice to say that at present no single explanation is adequate to cover all—or indeed many—cases, and that all the various factors must be included in any consideration of the ulcer problem, either from the point of view of etiology or from that of therapy.

*Symptomatology.*—The classical symptom of peptic ulcer is epigastric gnawing or burning pain occurring at a measurable time after the ingestion of food and relieved by the taking of food or antacid. Pain or discomfort usually occurs anywhere from half an hour to two hours after the intake of food or in the early morning hours. In all parts of the world there seems to be a general tendency for ulcer symptoms to be more prominent in the spring or fall. Although the most constant symptom of ulcer is pain, it should be pointed out that in older individuals and in the presence of massive hemorrhage pain may be entirely absent. It should also be noted that in the early stages of peptic ulcer the usual periodicity in relation to food ingestion may be entirely lacking, and pain may occur during, immediately after, or at a prolonged period after the intake of food. As the course of the disease becomes more evident, the symptoms tend to fall into the usual pattern. In uncomplicated ulcer, symptoms may last from a few days to a few weeks and may be followed by complete remission of symptoms for many months or even years. In spite of prolonged remissions it must never be forgotten that the tendency of peptic ulcer is to recur. Additional symptoms are those of nausea and vomiting of greater or less degree. The occurrence of these symptoms always suggests probable obstruction at the pylorus. A further point in symptomatology is that epigastric pain may frequently be transmitted directly through to the back, usually at the level of the eighth dorsal vertebra, and on rare occasions may be experienced only at this level in the back. Under these circumstances the diagnosis may be suggested by the periodicity of pain occurrence.

The interval of time elapsing between the ingestion of food and the appearance of ulcer pain presents no essential difference in gastric ulcer as contrasted with ulcer of the duodenum. Although ulcer pain is typically located in the mid-epigastrium, it may frequently be experienced to the right or left of the midline, rarely in the lower abdominal quadrants. Jejunal ulcer typically produces pain in the periumbilical area at a level distinctly lower than that associated with either gastric or duodenal lesions. Back pain frequently suggests the possibility of deep perforation of either a gastric or a duodenal lesion with involvement of the pancreas, but such a deduction is not necessarily a

valid one At times the severity of the pain may be extreme and may be completely unrelieved by either food or antacid Under such circumstances, it is almost certain that one is dealing with a deep penetrating relatively intractable lesion

Any consideration of the mechanism of pain in peptic ulcer must include several factors, of which acid gastric juice and the existence of open mucosal ulceration are the two most important Local hyperemia and swelling and probably local muscle spasm are almost certainly contributing factors Patients with peptic ulcer as a rule have no abnormality of appetite and are usually well nourished, but loss of weight may occur as a result of pyloric obstruction or because of restriction of food intake due to fear of ulcer pain Constipation is common

*Diagnosis —Physical Examination* Diagnostic physical findings are usually not present but localized tenderness in the epigastrium over the site of the ulcer is not uncommon In the presence of pyloric obstruction a distended stomach may be observed and if retention is of sufficient degree a succussion splash may be elicited Very rarely, a *tender epigastric mass* may be made out The finding of such a mass should never be accepted as evidence of a benign ulcerating lesion It should always be considered *malignant until proved otherwise*

*Laboratory Examinations* The value of gastric analysis has already received adequate comment *As a diagnostic method,* it gives little information of value except as a means of determining the degree of gastric retention Achlorhydria in the presence of a gastric lesion should be accepted as an indication that the ulcerating lesion is malignant until it is proved otherwise by direct examination *The finding of blood in the gastric* contents or in the stool is of importance but is in no way diagnostic of the nature of the lesion

FIG 200 —Duodenal ulcer with typical clover leaf deformity

*Roentgenologic Examination* In peptic ulcer examination by a competent radiologist is the most important of all diagnostic procedures Approximately 95 per cent of all ulcers causing symptoms can be demonstrated roentgenologically As a rule the most difficult ulcer to demonstrate by *x* ray examination is the small posterior wall,

duodenal ulcer which may be entirely missed or which may be visualized only when the patient is examined in the right oblique position The demonstration of a gastric or duodenal deformity provides proof merely of previous ulceration with healing An explanation of the patient's symptoms at the time of the examination can be obtained only by the demonstration of an actual crater Stomal and jejunal ulcers are particularly difficult to demonstrate Failure to obtain conclusive *x* ray evidence of peptic ulceration in no way precludes the diagnosis Indeed the presence of a typical ulcer history in the absence of other findings is sufficiently suggestive to warrant a trial of ulcer therapy

In the presence of major bleeding with hematemesis or marked melena the decision to carry out adequate *x* ray examination is open to some controversy According to some the danger attending a meticulous radiological examination in the presence of active bleeding seems to preclude the use of such a procedure at that particular time The experience of many including the author would seem to indicate however that in the presence of unexplained major hemorrhage from the upper gastro-intestinal tract the risk associated with an *x* ray examination is far less than the danger of not being able to demonstrate the site of hemorrhage If the precaution is taken to avoid active manipulation of the epigastric area during roentgenologic examination adequate fluoroscopic and spot film technique may be carried out which will demonstrate the lesion responsible for the bleeding in a very high percentage of cases Such information is extremely valuable in the event that surgical measures may have to be considered and with the above precautions there should be no hesitation in ordering such studies

*Gastroscopic Examination* This diagnostic procedure has provided additional assistance in the difficult differentiation between benign and malignant ulcerations of the stomach and direct visualization will frequently provide an easy diagnosis The appearance of a benign ulcer has already been described A grossly malignant lesion is usually characterized by a dirty base possibly overhanging irregular margins nodularity and rigidity In doubtful cases, gastroscopic observation may yield no definitive information but the additional possibility of obtaining biopsy material under direct vision through an operating gastroscope may make an absolute diagnosis possible in an otherwise difficult case It should be noted that gastric ulcers may occasionally be missed by the gastroscopist because of the existence of certain blind areas in the stomach itself It is also true that the gastroscopist is occasionally able to demonstrate a gastric lesion that has previously escaped the radiologist

*Cytological Examination* A final addition to our diagnostic armamentarium is that of cytological study of gastric residues These can be obtained either by careful washing of the stomach and aspiration of the material through a nasal tube, or by aspiration of the material through a gastroscope When properly stained by the Papanicalaou technique confirmatory evidence of gastric malignancy can frequently be obtained Occasionally this diagnostic procedure is the only one to give definitive results short of surgical exploration

*Treatment — Medical* The therapy of peptic ulcer in general can be separated into two distinct phases The first is that of promoting healing of the acute lesion The second is that of preventing recurrence Except in the most intractable ulcers healing usually can be obtained in a relatively short space of time by standard procedures The time required for the healing of an acute ulcer varies particularly in relation to the age of the patient In the younger individual healing usually takes place in three or four weeks In the later decades of life final healing may be postponed for several months The absence of pain or distress gives no guarantee as to the completeness of the healing process In fact it is usually true that in the larger ulcers a crater may still be demonstrated days or weeks after symptoms have subsided

The essential therapeutic measures for the *healing of acute ulcers* are well recognized They consist in adequate rest both physical and mental the administration of small frequent feedings of extremely simple foods and the use of antacid preparations antispasmodics and sedatives Physical rest

may be obtained by putting the patient to bed either at home or in a hospital. Freedom from emotional tension is an equally or even more important consideration, however, and this can best be obtained by removing the patient from obviously tense situations and at the same time, using the *principles of good psychotherapy* to obtain relief from anxiety and from situations that are likely to cause frustration or resentment. The use of the *barbiturates will frequently* supplement such measures and may be very effective. Dietary measures to be used during the therapy of an active ulcer are best regulated by providing small hourly feedings of bland food containing protein or fat and given throughout the waking hours. During the night, the interval between feedings may be increased to two hours, but the feedings should be given regularly, even to the extent of waking the patient, at least for the first few days of treatment. Partial neutralization of gastric acidity may be obtained by the use of one or more of the various antacid preparations now available. It should be pointed out that mixtures of free alkalies which include bicarbonate of soda should be avoided in the presence of any evidence of renal disease, inasmuch as symptoms of serious alkalosis *may be rather easily produced*. In this connection, it is of interest to point out that occasionally, the prolonged use of an ulcer regimen, with a high milk content and the *liberal use of antacid preparations containing* bicarbonate of soda may eventually result in the formation of calcium stones in the kidneys. Furthermore mixtures containing magnesium *tend to produce* abdominal cramps due to excessive peristalsis and diarrhea, and those containing calcium carbonate may be productive of rather severe constipation. The newer *preparations containing* aluminum hydroxide may also cause constipation unless combined *with* magnesium trisilicate or mineral oil. In many instances, the use of antacids is *not necessary* to control ulcer symptoms, and there is little evidence that their use demonstrably accelerates the healing process. When ulcer pain is difficult to control, however, they *should* be used as a regular part of therapy. Atropine or its derivatives, or more recently banthine, a synthetic antispasmodic, is frequently of extreme value in helping to control the symptoms of an acute peptic ulcer. If either of these drugs *is used, it should be* employed in dosages just short of those *giving the unpleasant side-effects—dryness* of the mouth, blurring of the vision, occa*sional irritability and disorientation* and in older people difficulty in voiding. The latter complication must be particularly guarded against in very elderly individuals, inasmuch as *bladder* stasis may result, a very troublesome complication. Often a useful routine where the patient is emotionally disturbed and suffering a good deal of distress is the periodic use of hypodermically administered sodium luminal and atropine sulphate in proper doses. Such a measure given in sufficient doses may provide tremendous relief of emotional tension and enable the physician to get control of the ulcer situation. If such a routine is employed, care should be taken to avoid over sedation. Although the exact mode of action of banthine may differ somewhat from that of the atropine derivatives, the general principle is identical and the drug constitutes merely one more antispasmodic that may at times be of use. In those instances where ulcer pain is extremely troublesome *in the night hours*, the *practice* of continuous gastric aspiration during the hours of sleep may give striking relief due to evacuation of the increased volume of nocturnal secretion *that is so characteristic of many* ulcer patients. In particularly intractable pain, the use of constant milk drip administered through an inlying nasal tube occasionally *may be indicated*. *As a routine procedure* however, it seems to have no justification since simpler methods will provide equally satisfactory results.

*In the acute cases* as *therapeutic measures* gradually become effective, it is proper *slowly to increase the interval between* feedings, diminish the number of night feed*ings, and reduce the amount of medication*. Simplification of procedure should be the aim in every instance, and any unnecessary or annoying measures, in the form either of *feedings or of drugs*, should be avoided once symptoms are well under control. A six-meal bland diet and measures directed toward obtaining adequate physical and

mental relaxation are often entirely adequate but careful therapy should be continued until all evidence of ulcer activity has disappeared

The problem of *preventing ulcer recurrences* is a much more difficult one and in many ways presents the chief therapeutic challenge in this disease Although it has been correctly stated that the cause of peptic ulcer is not known there can be no doubt that aggravating factors are well recognized and in many instances can be avoided Dietary regulation must be maintained with frequent simple feedings eaten slowly and on time as a fundamental principle of management This principle must be continuously observed The question of the use of alcohol tobacco coffee and tea becomes somewhat controversial in nature and at times is decided on the basis of emotional factors rather than on satisfactory clinical or experimental evidence The excessive use of coffee tea or caffeine-containing drinks is undoubtedly unwise and should be prohibited inasmuch as these substances stimulate gastric secretion Similarly alcohol is known to produce excessive gastric secretory activity For this reason in almost every instance it should be forbidden In occasional instances as a compromise measure the infrequent use of alcohol just before a main meal may be permitted in order to promote relaxation of the patient More than this should never be allowed The effect of smoking on gastric secretory function is not clear There are unquestionably numerous instances in which excessive smoking seems to promote the continuance of ulcer symptoms and the avoidance of smoking is accompanied by relief Whether the use of tobacco as such is really harmful because of its direct effect upon gastric function or whether it merely reflects increased nervous and emotional tension is a question to which at present there is no definitive answer It is certain from any point of view that excessive smoking should be avoided and in many instances complete avoidance of the use of tobacco is to be desired A point frequently overlooked is the fact that the type of food taken by a given patient is oftentimes of less importance than the regularity with which it is ingested Absolute regularity must be insisted upon as well as frequency and meals should be eaten slowly in a relaxed manner rather than rushed and taken under tension

The factor of emotional stress and strain cannot be adequately evaluated but all the existing evidence points to the fact that prolonged tension particularly tension involving resentment frustration and anxiety may be an important precipitating cause of ulcer recurrence It is therefore of the utmost consequence for the physician to become well acquainted with the problems of individual patients their living habits domestic relations work etc Orthodox psychotherapy is rarely needed although it may occasionally be useful An understanding physicain who has the confidence of his patient may frequently be very effective in preventing the build up of tensions and in helping the patient avoid undesirable situations Unless the patient as well as his ulcer can be managed the therapy of peptic ulcer is almost certain to be unsatisfactory

The factor of intercurrent infection is another variable which may precipitate the recurrence of an ulcer Except for the avoidance of exposure to obvious infective disease no particular measures can be taken to control this threat If however an ulcer patient acquires any intercurrent infection such as influenza common cold sore throat infectious diarrhea and the like it is of the utmost consequence to see that he is immediately placed on intensive ulcer therapy as if an active ulcer were present He should be kept in bed throughout the course of the infection and treated by any or all of the measures previously discussed

One point to emphasize is that many of the newer antibiotics such as aureomycin terramycin and chloromycetin may cause local gastric irritation with nausea and vomiting Such a result is extremely undesirable in an ulcer patient and the use of these drugs should be avoided unless they are absolutely indicated in order to manage an infectious episode Similarly the use of aspirin as a symptomatic measure in the control of arthritic pains or headaches should be avoided in patients with an ulcer history If salicylate therapy is necessary then the use of enteric-coated aspirin tablets is pref

erable in order to avoid gastric irritation. Finally, it should be pointed out that the therapeutic use of the corticosteroids ACTH and cortisone, is absolutely contraindicated in any patient in whom an ulcer is suspected or is known to have previously occurred. These agents stimulate gastric secretion to a very great degree, and numerous instances are already on record in which corticosteroid therapy has been complicated by the recurrence of a peptic ulcer with perforation or hemorrhage.

Careful radiation therapy of the gastric area may constitute a valuable but unpredictable therapeutic measure in otherwise intractable cases.

*Complications.*—The important complications of peptic ulcer are acute perforation, hemorrhage and obstruction.

*Acute perforation* is a frequent complication of peptic ulcer and, unless quickly recognized, is extremely dangerous. The diagnosis of acute perforation is rarely difficult. In most instances the patient is suddenly aware of acute upper abdominal pain which is extremely severe and may be aggravated by motion or by breathing. If there is much leakage through the perforation, fluid and air may spread under one or the other diaphragm with pain radiating typically to the trapezius ridge. As a rule the pain is so intense that the patient holds himself in a very rigid fashion. Palpation of the abdomen reveals boardlike rigidity and respirations are short and rapid. The patient may be cold, and at first, his pulse is not rapid. His temperature may be subnormal. If the condition remains unrecognized and a serious leakage has occurred, the patient's condition rapidly deteriorates with a steadily rising pulse. If operation is not performed, general peritonitis may ensue. Hippocratic facies may be noted, and the patient may die in the course of a few days. The differential diagnosis is usually not difficult, particularly if it is known that the patient has a peptic ulcer. The condition must be differentiated from acute pancreatitis, acute appendicitis, coronary thrombosis, lobar pneumonia, biliary or renal colic, and tabetic crisis. The absence of shock so commonly noted in acute pancreatitis and the boardlike rigidity of the abdomen, together with the suddenness of the onset of symptoms, are the most important diagnostic points. Very occasionally, leakage may occur from a perforated ulcer, with drainage into the pelvis, thus simulating a ruptured ectopic pregnancy or a twisted ovarian cyst. In mesenteric thrombosis and in intestinal obstruction, pain is apt to be peristaltic in nature and abdominal rigidity is much less marked. A film of the abdomen may reveal air under the diaphragm and this constitutes important confirmatory evidence in favor of a perforated ulcer. Films should be taken with the patient in the horizontal and sitting posture if this is possible. Small perforations may occur which may spontaneously seal off. Under such conditions, the patient rarely presents the characteristic picture suggested above.

In almost every instance where the diagnosis is made, surgical interference is indicated and should be carried out as soon as possible. The longer the period of time that elapses between perforation and operation, the poorer the prognosis. Perforation of a peptic ulcer accounts for the vast majority of ulcer deaths, but if operation is performed within 10 or 12 hours of the accident, the survival rate is high. If perforation occurs shortly after a meal, the danger is greater because of the greater spillage of infected contents into the abdominal cavity. The operation of choice is that of closure, and, as a rule, no further procedure should be carried out. Antibiotics should be used in most instances to prevent spreading peritonitis, and in case in which conservative measures seem indicated after proper surgical consultation, antibiotic treatment is definitely indicated. Obviously, the ingestion of food or fluid by mouth should be carefully avoided once the diagnosis is suspected. In certain cases, the patient may not be seen by a doctor in the early stages of the complication, or a correct diagnosis may not have been made for many hours after the event has occurred. If this is the case and a delay of many hours has resulted, then operation is contraindicated for the moment, and the patient should be treated most conservatively, feeding or the giving of any fluids by mouth being forbidden. The patient should be placed in a semi-upright position, kept under continuous morphine administration.

and given adequate doses of penicillin streptomycin or possibly aureomycin by the intravenous route Such measures however are justified only where the diagnosis has been delayed beyond the early stages of the complication In recent years there has been an attempt to treat patients having perforated peptic ulcers without operative interference and good results have been claimed In general however present opinion would seem to indicate that the only proper therapeutic approach to the problem of perforation is early diagnosis and early operative intervention It should be added that successful surgical treatment of an acute perforation of peptic ulcer does not solve the ulcer problem it merely handles the existing emergency Subsequent perforations may occur and the ulcer problem continues unchanged regardless of surgical closure of the perforation

*Chronic perforation* may occur in which a deeply penetrating ulcer breaks through the wall of the stomach and becomes walled off in the body of the pancreas or liver Such an occurrence represents merely the extension of a very active inadequately treated ulcer and does not require immediate surgical treatment Chronic perforation of a jejunal ulcer may result in a gastrojejunocolic fistula a condition which demands elective surgery but does not result in an acute emergency

*Massive hemorrhage* occurs as a serious complication of peptic ulcer in a high percentage of patients It may become evident either by the vomiting of gross blood or by the passage of tarry or bloody stools If bleeding is sufficient in amount and occurs fairly rapidly the stools may contain loose or semi coagulated material resembling currant jelly If bleeding occurs more slowly the material becomes black in color and pitchy in consistency The variation in the character of the stool after massive bleeding from an ulcer depends very definitely upon the two factors noted—speed and quantity As little as 60 cc of blood may produce a tarry stool Massive bleeding may occur with no vomiting whatever Or vomiting may be delayed in which event the vomitus will resemble coffee grounds or may even consist of black rather than reddish or brownish liquid The mortality rate from gross hemorrhage probably is in the vicinity of 3 or 4 per cent of all cases For those over forty five or fifty the mortality rate steadily increases due possibly to the fact that in older people arterial bleeding is less readily controlled Although statistics vary hemorrhage in younger individuals probably carries a risk of about 1 or 2 per cent After the sixth decade the risk may be as high as 10 or 15 per cent These figures however undoubtedly are modified by the adequacy of treatment during the acute episode

The symptoms associated with massive hemorrhage are essentially those of acute blood loss with weakness dizziness headache extreme thirst sweating rapid respirations syncope and collapse The hemorrhage may have been preceded by a period of epigastric pain typical of peptic ulcer but in very many instances pain is lacking and bleeding may occur totally without warning When pain has been present it is commonly noted that discomfort ceases with the onset of bleeding If bleeding continues the pulse rate rises the blood pressure drops and the pulse pressure becomes reduced The patient may go into shock unless bleeding ceases spontaneously or blood is replaced by transfusions The red-cell count the hemoglobin concentration and the hematocrit may remain practically normal for some hours but gradually drop as plasma volume is maintained by dilution In the presence of major hemorrhage there is a rise in the nonprotein nitrogen of the blood which remains elevated as a rule for several days Usually bleeding stops spontaneously but if a large artery has been eroded either the pancreatico-duodenal or the gastric coronary artery hemorrhage may be continuous with a steady increase in associated symptoms of blood loss

The diagnosis of upper gastrointestinal bleeding is usually obvious but in the absence of a known ulcer history it is frequently impossible to determine the source of bleeding immediately Physical examination is of the utmost importance in those instances in which the existence of a peptic ulcer is not known The presence of slight jaundice spider angiomata a spleen that is enlarged to percussion or a palpable liver

erable in order to avoid gastric irritation Finally, it should be pointed out that the therapeutic use of the corticosteroids ACTH and cortisone is absolutely contraindicated *in any patient in whom an ulcer is suspected* or is known to have previously occurred These agents stimulate gastric secretion to a very great degree, and numerous instances are already on record in which corticosteroid therapy has been complicated by the recurrence of a peptic ulcer with perforation or hemorrhage

Careful radiation therapy of the gastric area may constitute a valuable but unpredictable therapeutic measure in otherwise intractable cases

*Complications* —The important complications of peptic ulcer are acute perforation hemorrhage and obstruction

*Acute perforation* is a frequent complication of peptic ulcer and unless quickly recognized, is extremely dangerous The diagnosis of acute perforation is rarely difficult In most instances the patient is suddenly aware of acute upper abdominal pain which is extremely severe and may be aggravated by motion or by breathing If there is much leakage through the perforation fluid and air may spread under one or the other diaphragm with pain radiating typically to the trapezius ridge As a rule the pain is so intense that the patient holds himself in a very rigid fashion Palpation of the abdomen reveals boardlike rigidity and respirations are short and rapid The patient may be cold and, at first, his pulse is not rapid His temperature may be subnormal If the condition remains unrecognized and a serious leakage has occurred the patient s condition rapidly deteriorates with a steadily rising pulse If operation is not performed general peritonitis may ensue Hippocratic facies may be noted and the patient may die in the course of a few days The differential diagnosis is usually not difficult particularly if it is known that the patient has a peptic ulcer The condition must be differentiated from acute pancreatitis acute appendicitis coronary thrombosis, lobar pneumonia biliary or renal colic, and tabetic crisis The absence of shock so commonly noted in acute pancreatitis and the boardlike rigidity of the abdomen, together with the suddenness of the onset of symptoms, are the most important diagnostic points Very occasionally leakage may occur from a perforated ulcer with drainage into the pelvis thus simulating a ruptured ectopic pregnancy or a twisted ovarian cyst In mesenteric thrombosis and in intestinal obstruction, pain is apt to be peristaltic in nature and abdominal rigidity is much less marked A film of the abdomen may reveal air under the diaphragm, and this constitutes important confirmatory evidence in favor of a perforated ulcer Films should be taken with the patient in the horizontal and sitting posture, if this is possible Small perforations may occur, which may spontaneously seal off Under such conditions the patient rarely presents the characteristic picture suggested above

In almost every instance where the diagnosis is made surgical interference is indicated and should be carried out as soon as possible The longer the period of time that elapses between perforation and operation the poorer the prognosis Perforation of a peptic ulcer accounts for the vast majority of ulcer deaths but if operation is performed within 10 or 12 hours of the accident the survival rate is high If perforation occurs shortly after a meal the danger is greater because of the greater spillage of infected contents into the abdominal cavity The operation of choice is that of closure and, as a rule no further procedure should be carried out Antibiotics should be used in most instances to prevent spreading peritonitis and in case in which conservative measures seem indicated after proper surgical consultation, antibiotic treatment is definitely indicated Obviously, the ingestion of food or fluid by mouth should be carefully avoided once the diagnosis is suspected In certain cases the patient may not be seen by a doctor in the early stages of the complication, or a correct *diagnosis may not have* been made for many hours after the event has occurred If this is the case and a delay *of many hours has resulted then operation* is contraindicated for the moment and the patient should be treated most conservatively *feeding or the giving of any fluids by* mouth being forbidden The patient should be placed in a semi upright position kept under continuous morphine administration

cancer and the like if an ulcer is not present The technique of such an examination has already been discussed and requires close coöperation between the radiologist and the physician If massive bleeding from an ulcer does not stop within a reasonable length of time and an adequately trained surgeon is available radical surgery is occasionally indicated as a life-saving procedure Such a decision is at times extremely difficult and operation should not be attempted unless very competent surgical skill is at hand Subtotal resection as an emergency procedure is not desirable in most instances but uninterrupted bleeding for two or three days may make such a decision necessary for in this event the ulcer has eroded into a major vessel and caused a situation that can be handled only by heroic measures With the availability of trained surgeons and an adequate supply of blood such emergency surgery has lost many of its terrors The persistence of bleeding with a fairly rapid *rate of blood loss justifies the administration* of whole blood at a much more rapid rate than that usually employed and at times the blood may have to be given very rapidly in order to carry the patient until proper surgery can be performed

If the episode of major bleeding terminates successfully under medical management consideration of future treatment should then be discussed In many instances elective subtotal gastrectomy should be planned in order to reduce the risk of future hemorrhage There is no unanimity of opinion as to such a decision however and it must always be a matter of individual decision between the physician and the consulting surgeon In older individuals the risk of major bleeding from peptic ulcer is such that surgical intervention at a time when the ulcer is entirely under control would seem to be the safer and more conservative measure In patients who are poor operative risks or in individuals who have never carried out adequate ulcer therapy prior to their hemorrhage conservative medical measures may be proper Such measures should always be accompanied however by a distinct understanding that should subsequent hemorrhages occur subtotal gastrectomy will be performed If elective surgery is performed the patient should understand clearly that this does not entirely preclude the possibility of future hemorrhage and that reasonable regulation of diet and living habits still remains a fundamental consideration

A third complication is that of *pyloric obstruction* Temporary obstruction is frequently encountered as a result of the edema and spasm secondary to an active ulcer in the close proximity of the pylorus Such an occurrence represents a temporary situation which usually responds satisfactorily to good medical management It is not easily differentiated from pyloric obstruction due to cicatricial stenosis at or near the pylorus until the patient has been observed for an appreciable period of time The symptoms of obstruction are common to both situations and consist of epigastric fullness nausea and vomiting Pain may or may not be present but is more likely to be encountered in the presence of an active ulcer In the old cicatrizing lesion pain is a less *prominent feature and gradually increasing* evidence of gastric stasis without pain is the most characteristic symptom Unless the pylorus is completely occluded it is usually found that the vomitus contains bile-stained material which indicates a certain degree of patency The degree of gastric stasis can be most readily determined by gastric aspiration which can and should be carefully measured and recorded together with the amount of vomited material in order to keep an adequate record of daily fluid and electrolyte loss Where minor degrees of stasis are present small frequent feedings should be employed in the manner already described for the treatment of acute peptic ulcer With more complete obstruction such measures may still be utilized but aspiration should be carried out preferably in the morning and in the evening to determine the total amount of stasis On the balance sheet the amount of orally administered fluid should be recorded as well as the amount obtained by aspiration A daily record of intake and output is an absolutely essential measure if proper fluid and electrolyte replacements are to be made It is also essential in order to make a correct and timely decision for operative interference if such is necessary Decision to operate

that is felt by gentle examination, should lead to suspicion of bleeding from esophageal varices rather than from an ulcer, although the two conditions may be coexistent. A visible abdominal mass, other than the liver, should, *of course, suggest the possibility* of gastric cancer, but major bleeding from cancer of the stomach is relatively uncommon. Cautious physical examination may yield no information, and vigorous manipulation and palpation should be avoided. If physical signs other than those associated with active bleeding are not present, the most logical explanation is that of bleeding from a peptic ulcer, inasmuch as this is by far the most common cause of upper gastrointestinal hemorrhage. Further diagnostic measures should be postponed until it is certain that the bleeding has stopped or that the patient is not in shock.

The immediate treatment that is indicated is that of bed rest, elevation of the foot of the bed, and sedation. The administration of morphine to relieve restlessness is the traditional therapeutic measure. In the opinion of the author, the use of morphine is contraindicated, inasmuch as it may produce nausea and vomiting and may cause associated duodenal spasm. Probably a wiser procedure is to administer sodium phenobarbital subcutaneously and to procure further sedation by its periodic use as indicated. At the same time preparation should be made to replace blood loss by whole blood transfusion. If the patient is in shock and blood is not immediately available, solutions of glucose and saline may be given by slow intravenous drip, or plasma may be used. The use of whole blood is preferable, however, and wherever massive hemorrhage has occurred it is probably good judgment to transfuse slowly until it is perfectly certain that there is no danger of shock. From that point on, the use of blood transfusions should be regulated by the level of hematocrit or the hemoglobin level as determined at fairly frequent intervals. Except in rare instances, the blood should be given at a very slow rate. Exceptions to this are rare and will be noted subsequently. In most instances small careful feedings of bland protein-containing food should be administered, once vomiting has ceased. These feedings may be given at half hourly or hourly intervals in amounts ranging from 30 to 60 cc. of milk, or if desired they may be given by constant milk drip; the latter is rarely needed. The program of feeding outlined by Meulengracht in bleeding cases embodies the same principle but permits the use of a variety of foods. As a rule, in the early stages of feeding after hemorrhage it would seem wise, however, to limit the diet to small quantities of food such as whole milk, milk, and lime water or gelatine, as originally suggested by Andresen. The use of amino acids, as suggested by Co Tui, has certain theoretical advantages, but the distaste that most patients have for amino acid preparations is such that ordinarily other types of feeding are more easily tolerated and just as valuable in neutralizing gastric acidity and in providing calories and protein. If vomiting continues, temporary avoidance of oral feeding may be necessary, but this is usually not the case. Constant observation of pulse, blood pressure, pulse pressure, and the general appearance of the patient is of fundamental importance, and evidences of recurrent bleeding or incipient shock should be quickly noted and treated by further careful transfusions. During the early phases of treatment the use of antacids is probably not necessary in the presence of adequate oral feedings. Once the situation seems to be under control, the addition of antacid preparations may be desirable. The replacement of blood by transfusion should be sufficient in amount to maintain the patient well above shock level but should not aim at raising the hemoglobin to high levels. In general, it will be found that it is desirable to maintain a somewhat higher level of hemoglobin in older individuals than is necessary for the younger age group. Once it is certain that bleeding has stopped, therapeutic measures should be carried out as they would be during the course of acute ulcer therapy. If the source of bleeding is not clear, it is important to recognize the wisdom of careful *x*-ray studies just as soon as hemorrhage has ceased. It is extremely important to obtain precise information, if possible, as to the location of the lesion if it is an ulcer, or to demonstrate the existence of other causes, such as esophageal varices

or adjacent jejunum are relatively common. The demonstration of a stomal or jejunal ulcer after posterior gastrojejunostomy may have as high an incidence as 25 per cent or more. Stomal or jejunal ulcer may occur after subtotal gastrectomy, but it is relatively uncommon. The incidence probably is below 5 per cent. When it does occur, the question should be immediately raised whether the resection was adequate—particularly whether the entire pyloric antrum was removed. Failure to accomplish the latter results in stomal ulceration in a very high percentage of cases, and subsequent removal of the remaining pyloric antrum almost invariably controls the situation. Otherwise the problem of stomal or jejunal ulcer presents a very difficult therapeutic problem. At times further radical resection of the stomach is in order. Another maneuver frequently accompanied by a reasonable degree of success is that of vagal section.

A complication of jejunal ulcer is that of gastrojejunocolic fistula, and this invariably requires extremely radical surgery. Such a complication may be encountered in between 5 and 10 per cent of patients with stomal or jejunal ulcers.

In recent years the performance of bilateral vagal section, with or without associated gastrojejunostomy, has been carefully studied by various surgeons and physicians. Vagotomy, when adequately performed, undoubtedly results in a complete inhibition of psychic gastric secretion, in marked reduction of gastric motility, and in the control of otherwise uncomplicated ulcer symptoms. When performed as a single procedure, experience has shown that ulcer recurrences may be expected in an appreciable number of instances. It is therefore not definitive surgery. If combined with a posterior gastroenterostomy, the results may be much more successful, and enthusiasm for this procedure is properly based upon the experiences of Dragstedt and Palmer. It is fair to comment, however, that more years must elapse before the procedure can be properly evaluated. The ultimate value of such a combined operation will depend upon its ability to control symptoms over a period of many years without ulcer recurrence. It has the theoretical advantage that it leaves the patient with an intact stomach, and in the absence of obstruction permits a reasonable amount of food to proceed through the pylorus into the duodenum with the accompanying physiological stimulation of duodenal and pancreatic secretions.

*Complications of Surgery.*—Any discussion of ulcer surgery should include two considerations aside from the immediate risk of operation and the subsequent possibility of stomal or jejunal ulcer. One possible complication is the so-called *dumping syndrome*. Symptoms of this syndrome may occur either after subtotal gastrectomy or after simple gastrojejunostomy. In the first weeks after operation it is not at all uncommon to encounter this particular set of symptoms, but in the vast majority of cases adjustment takes place so that it does not constitute a major problem in later months. In from 10 to 15 per cent of individuals who have either a subtotal gastrectomy or a gastrojejunostomy, troublesome symptoms are encountered which appear either a few minutes after the intake of food or after a delay of from two to four hours. In all but a few cases symptoms occur shortly after eating—epigastric fullness, discomfort, occasionally pain, accompanied by a feeling of weakness or giddiness, excessive sweating and tachycardia or bradycardia, with alterations in blood pressure, either elevation or reduction. In rare instances, actual syncope may occur. Although suggestive of a hypoglycemic attack, a reduction in the blood sugar is not present, and the symptoms in all probability are the result of an active overfilling of the proximal jejunum and a violent vasomotor disturbance secondary to autonomic nervous stimulation. Relief is usually obtained by lying in a horizontal position for a few minutes, though sometimes resting thus for half an hour or more may be required. The symptoms may be relatively mild or they may be so intense that the patient may fear the act of eating to a degree which precludes adequate nutrition. The nature of the ingested food is of some importance but does not determine the appearance of symptoms. Sugary or highly sweetened foods seem to provide one factor in the production of attacks. In some individuals the use of milk seems to be a pre

should depend upon the continuance of obvious obstruction while the patient is under close observation. If an adequate caloric intake with sufficient fluid cannot be given by mouth within a reasonable length of time surgery is mandatory. If however, evidence of gastric stasis diminishes daily, conservative medical measures should be continued, with the expectation that satisfactory control of the immediate situation will be obtained on the subsidence of the active ulcer. Where there has been prolonged excessive vomiting before admission to the hospital chemical determinations of serum electrolytes are frequently indicated in order to plan for the proper administration of sodium chloride, and potassium ions. In addition, it is important to attempt to meet caloric needs by proper parenteral administration of glucose or glucose and amino acids, in solution. This is particularly true if the situation seems to be approaching a decision for surgical intervention inasmuch as the depleted patient may tolerate surgery very poorly. It is obvious that estimates of the obstructing lesion should be confirmed by careful radiological study but it should be pointed out that such studies are of little value unless the stomach is completely emptied by previous aspiration before a barium meal is taken. In the case of pyloric obstruction secondary to an acute ulcer with little or no cicatricial stenosis the use of atropine and sedation may be the most important therapeutic measure other than routine careful feeding. Conversely where cicatricial stenosis of major degree is encountered and there is marked dilatation of the stomach from long standing stenosis atropine or other antispasmodics are probably contraindicated. As already noted marked cicatricial stenosis is in itself an indication for operative interference and if the patient can be properly called a good operative risk subtotal gastrectomy is the operation of choice. Occasionally posterior gastrojejunostomy may be the desirable procedure. In patients having repeated attacks of pyloric obstruction secondary to ulcer recurrences, surgery may eventually be necessary, either because of progressive stenosis secondary to healing or because of continued failure to control the ulcer situation to a degree where the patient can lead a useful life.

Perforation and hemorrhage may coëxist and such a complication presents an extremely difficult problem. The indications for surgery are clear as soon as the diagnosis of perforation is established. The treatment of bleeding will of necessity depend upon findings at operation but in any event replacement of blood in adequate amounts is absolutely essential.

*Intractability.*—One final complication of peptic ulcer that requires consideration of surgery must be briefly mentioned—namely, "intractability." Such a term is necessarily vague and difficult of definition. Frequently intractability suggests that medical management by the physician has been totally inadequate. In many instances, it implies a lack of understanding of the fundamental principles of ulcer management both by the physician and by the patient. In other cases however intractability may imply failure of adequate medical therapy to control ulcer symptoms in such a way as to permit the patient to carry on a normal existence. Under these circumstances ulcer surgery is certainly indicated. In still other instances, intractability may be due to the fact that the patient is essentially a neurotic individual in which case either medical or surgical treatment may fail completely to control not only the ulcer symptoms but other complaints characteristic of the neurosis. In this combination of a neurotic patient and chronic peptic ulcer surgery is usually contraindicated because the patient will not be rendered a useful and relatively symptom free individual. Psychotherapy is the only approach to the problem and even this is often entirely unsuccessful.

*Surgical Treatment.*—The surgical treatment of peptic ulcer has already been alluded to. As on other aspects of the ulcer problem complete unanimity of opinion does not exist but the view of most experienced clinicians suggests that subtotal gastrectomy is at present the operation of choice if a competent sugeon is available and the proper indications exist. The procedure of posterior gastroenterostomy is usually ill advised inasmuch as ulcer recurrences at the original site or more frequently in the stoma

or adjacent jejunum are relatively common The demonstration of a stomal or jejunal ulcer after posterior gastrojejunostomy may have as high an incidence as 25 per cent or more Stomal or jejunal ulcer may occur after subtotal gastrectomy but it is relatively uncommon The incidence probably is below 5 per cent When it does occur the question should be immediately raised whether the resection was adequate—particularly whether the entire pyloric antrum was removed Failure to accomplish the latter results in stomal ulceration in a very high percentage of cases and subsequent removal of the remaining pyloric antrum almost invariably controls the situation Otherwise the problem of stomal or jejunal ulcer presents a very difficult therapeutic problem At times further radical resection of the stomach is in order Another maneuver frequently accompanied by a reasonable degree of success is that of vagal section

A complication of jejunal ulcer is that of gastrojejunocolic fistula and this invariably requires extremely radical surgery Such a complication may be encountered in between 5 and 10 per cent of patients with stomal or jejunal ulcers

In recent years the performance of bilateral vagal section with or without associated gastrojejunostomy has been carefully studied by various surgeons and physicians Vagotomy when adequately performed undoubtedly results in a complete inhibition of psychic gastric secretion in marked reduction of gastric motility and in the control of otherwise uncomplicated ulcer symptoms When performed as a single procedure experience has shown that ulcer recurrences may be expected in an appreciable number of instances It is therefore not definitive surgery If combined with a posterior gastroenterostomy the results may be much more successful and enthusiasm for this procedure is properly based upon the experiences of Dragstedt and Palmer It is fair to comment however that more years must elapse before the procedure can be properly evaluated The ultimate value of such a one based operation will depend upon its ability to control the symptoms over a period of [illegible] years without ulcer recurrence It has the theoretical advantage that it leaves the patient with an intact stomach and in the absence of obstruction permits a reasonable amount of food to proceed through the pylorus into the duodenum with the accompanying physiological stimulation of duodenal and pancreatic secretions

*Complications of Surgery* —Any discussion of ulcer surgery should include two considerations aside from the immediate risk of operation and the subsequent possibility of stomal or jejunal ulcer One possible complication is the so-called *dumping syndrome* Symptoms of this syndrome may occur either after subtotal gastrectomy or after simple gastrojejunostomy In the first weeks after operation it is not at all uncommon to encounter this particular set of symptoms but in the vast majority of cases adjustment takes place so that it does not constitute a major problem in later months In from 10 to 15 per cent of individuals who have either a subtotal gastrectomy or a gastrojejunostomy troublesome symptoms are encountered which appear either a few minutes after the intake of food or after a delay of from two to four hours In all but a few cases symptoms occur shortly after eating—epigastric fullness discomfort occasionally pain accompanied by a feeling of weakness or giddiness excessive sweating and tachycardia or bradycardia with alterations in blood pressure either elevation or reduction In rare instances actual syncope may occur Although suggestive of a hypoglycemic attack a reduction in the blood sugar is not present and the symptoms in all probability are the result of an active overfilling of the proximal jejunum and a violent vasomotor disturbance secondary to autonomic nervous stimulation Relief is usually obtained by lying in a horizontal position for a few minutes though sometimes resting thus for half an hour or more may be required The symptoms may be relatively mild or they may be so intense that the patient may fear the act of eating to a degree which precludes adequate nutrition The nature of the ingested food is of some importance but does not determine the appearance of symptoms Sugars or highly sweetened foods seem to provide one factor in the production of attacks In some individuals the use of milk seems to be a pre-

cipitating factor, although the symptoms are in no way suggestive of an allergic response. The *volume of the meal* may be important, and in most instances where symptoms are at all prominent, frequent feedings of small amounts may be helpful. Atropine or banthine taken in adequate doses fifteen or more minutes before the intake of food may prevent attacks or minimize their severity. In a few instances, the symptoms are so extreme that they result in a totally inadequate food intake with an accompanying severe malnutrition. At times they are *essentially very intractable*. They tend to occur in the more reactive rather neurotic individuals. The dumping symptoms which occur several hours after the intake of food are relatively uncommon and may be a reflection of a lowered blood sugar. This is not always the case, as *proved by chemical determinations of the level of sugar in the blood* but symptoms are not infrequently benefited by the immediate administration of food. As a rule they are much less severe and less incapacitating than those symptoms already described.

A second complication of subtotal gastrectomy is that of *inadequate food absorption* and consequent malnutrition which may be quite independent of dumping symptoms. It has been shown by various investigators *that patients with this complication tend to* lose excessive amounts of fat and slightly excessive amounts of nitrogen in the stools. Such is invariably the case in the first few days or weeks after the operation but adjustment usually takes place without difficulty. The explanation of this phenomenon is not clear. To date, it has not been shown to be due to inadequate pancreatic digestion or to any other known factor. It is possible that it is dependent upon the removal of the lower portion of the stomach which may produce a secretion capable of affecting the physiological absorption of lipoids and to a lesser extent other substances. Therapeutic measures so far have been *quite ineffective in* controlling this particular complication which is serious because it results in chronic undernutrition. The oral use of certain detergents, such as 'Tween 80,' to improve the emulsification of fat has, in some instances, been helpful in improving fat absorption. In most instances, the most important therapeutic measure consists in the administration of excessive amounts of food. Such a measure is difficult and is not easily tolerated by most patients. It is essential, however, if the wastage of calorific material is to be covered to a sufficient degree to permit maintenance of weight or gain in weight. In order to accomplish this, diets *high in concentrated foods* and relatively low in total bulk must be administered.

BENIGN GASTRIC ULCER VERSUS GASTRIC CARCINOMA.—Up to the present point, *gastric ulcer has been discussed in the same* category as duodenal ulcer. Additional consideration, however, must be given to the fact that benign gastric ulcer and carcinoma of the stomach may be readily confused. The controversy as to the possible degeneration of a benign ulcer into a car*cinomatous lesion has not been settled and* is for practical purposes purely academic. The important consideration is that the demonstration of an ulcerating lesion of the stomach imposes the obligation of ruling out the probability of gastric cancer before final therapeutic decisions can be made. Furthermore, no physician has a right to accept the responsibility of conservative medical care of a proved gastric ulcer unless he is fully prepared to follow the patient's course for an *indefinite time with periodic checkups*. Differentiation between a benign and malignant lesion of the stomach in doubtful cases is never definitive. In obvious cancer of the stomach the radiological findings are clear cut, and there need be no hesitation in making the diagnosis. The real problem is encountered where an ulcerating lesion appears to be benign and therefore should be treated conservatively if possible. Clinical experience shows that malignant lesions occur as a rule in the later decades whereas benign ulcer most commonly appears in the earlier decades of life. Typically the history of gastric cancer is relatively short, that of a benign lesion as a rule covers a period of years. Neither fact is in any way conclusive in making individual diagnoses. On physical examination the finding of an epigastric mass may, *on rare occasions*, be associated with a benign lesion but this fact should never be accepted as a justification for con

servative measures The finding of a palpable tumor in relation to an ulcerating lesion of the stomach or pylorus should always lead to a decision in favor of radical gastric surgery Gastric analysis in carcinoma of the stomach may reveal normal or relatively normal gastric secretion Therefore the finding of normal acid values does not preclude the possible presence of malignancy On the other hand achlorhydria after histamine stimulation in a patient with a demonstrated gastric lesion should always be taken as presumptive evidence of cancer Cytological studies of gastric contents by well trained observers may be of real help but negative findings offer no assurance that the lesion is benign Positive findings are diagnostic Radiological examination of the stomach may suggest a benign lesion because of the location of the ulcer and the absence of rigidity and of interruption to normal peristaltic waves Most benign lesions are found in the middle of the lesser curvature The majority of malignant lesions are encountered in the region of the antrum All these criteria are of relative value however and cannot give complete assurance as to the nature of the process Gastroscopic observations may show the clean punched-out ulcer characteristic of a benign lesion or one with the irregular partially undermined edges and dirty base typical of malignancy An ulcer of apparently benign appearance however may contain early malignant changes which cannot be determined by gastroscopic observation Additional evidence may be obtained by biopsy through the operating gastroscope but only positive findings are definitive In spite of the fact that an absolute diagnosis of a benign lesion is not possible it is probably unwise and unnecessary to adopt the radical attitude that every gastric ulceration requires radical resection If the physician is prepared to follow the patient carefully it is frequently proper to elect a course of watchful waiting In a patient with a gastric ulcer who has a typical ulcer history a normal amount of free acid a negative cytological study and a satisfactory gastroscopic examination confirming the benign appearance of the lesion routine medical ulcer therapy may be instituted This should be done with the understanding that careful x ray and/or gastroscopic checkups will be performed at regular intervals Evidence of healing should be obtained by x ray examination at an interval of no longer than one month after the institution of medical treatment If progress is apparently satisfactory and the size of the crater has appreciably diminished then a second x ray or gastroscopic examination should be performed at the end of another three or four weeks If at this time the ulcer crater has disappeared and symptoms are completely under control then it may be proper to continue further medical management Checkup examinations should be made periodically at intervals of several months or at any time that symptoms recur It should never be forgotten that apparently complete healing may occur in a small ulcerated cancer The mucosa may bridge the area of malignant involvement so that all evidence of ulceration has disappeared Fortunately such an occurrence is rare Failure to show evidence of healing in a reasonable length of time or failure to control symptoms that recur should require a review of the entire situation and in many instances surgical intervention should be chosen as the proper therapeutic move This is particularly true where gastric ulceration is demonstrated in the region of the pyloric antrum or the prepyloric area Ulcers along the greater curvature of the stomach or in unusual areas other than the mid lesser curvature should always be viewed with extreme suspicion It is better occasionally to resect a benign lesion that to miss an early diagnosis and forfeit the opportunity for a successful cure of gastric cancer

Cancer of the first portion of the duodenum is so rare that consideration of this possibility need not be seriously entertained except in cases in which the x ray findings are very abnormal or the lesion and the patient s symptoms are unusually intractable

Gastric Tumors —Gastric tumors include those of epithelial origin such as adenomas papillomas adenomatous polyps and adenocarcinomas and also the less common tumors of mesenchymal origin The latter include tumors classified as fibromas

myomas leiomyomas, sarcomas, dermatoid cysts hemangiomas, lipomas and the various forms of lymphomatous tumors The symptoms of gastric tumor are in no way diagnostic They vary according to the complications arising from the tumor itself such as ulceration bleeding or the development of the tumor to a size sufficient to cause obstruction Thus the presence of a leiomyosarcoma may be first suspected when the patient develops symptoms of ulceration with or without bleeding Adenomatous polyps for example may present frank gastric bleeding is the initial symptom Symptoms directly due to the tumor may be entirely absent but minor bleeding may occur with resulting anemia which necessitates a search for the source of the hemorrhage The diagnosis of tumor in the absence of a visible or palpable mass in the epigastrium will be entirely dependent upon radiological or gastroscopic studies Gastric polyps may be benign or malignant but once demonstrated should usually be treated by surgical removal inasmuch as the probability of malignancy or of malignant degeneration exceeds the risk of surgery In pernicious anemia and in atrophic gastritis polyps are occasionally encountered Bleeding with resulting anemia is the usual clinical finding and such polypi should always be resected, either by local removal or by subtotal gastrectomy

Fig 201 —Adenomatous polyp of the stomach adjacent to a fungating carcinoma (Herbut s Surgical Pathology)

*Adenocarcinoma* of the stomach is extremely common and early diagnoses are still too infrequent with the result that the mortality rate associated with this condition is extremely high Gastric cancer is probably responsible for a greater number of deaths than any other form of cancer The etiology is unknown but heredity may play an important role It is rarely encountered until the third decade and is most commonly found after the age of thirty five Symptomatically gastric cancer may be silent until it is far advanced As already indicated even when symptoms are present the history is relatively short and may frequently be measured in weeks or a few months When symptoms are present they usually are characterized by loss of appetite and diminished food intake with loss of weight and relatively mild epigastric distress It is important to point out that one of the most

common symptoms is that of gradually increasing constipation without any obvious cause At times the story may mimic that of peptic ulcer, but this is the exception rather than the rule, inasmuch as pain may occur during the meal and frequently is not relieved either by the intake of food or by the use of antacids Nausea and vomiting are not uncommon and are not necessarily associated with definite obstruction The vomitus may contain blood and hematemesis or tarry stools may be early clinical manifestations of the disease Massive bleeding is not particularly common although continuous oozing is rather characteristic with a resulting severe anemia As a rule the anemia is that associated with blood loss but occasionally macrocytic anemias are encountered Perforation may occur but is relatively uncommon Physical examination is all too frequently noncontributory except for evidences of anemia and loss of weight A palpable mass may be encountered and it is important to search for evidences of hepatic enlargement the existence of a Virchow node or metastatic lesions in the ovaries or on the rectal shelf Except for cytological studies of the gastric contents laboratory examinations yield no definite diagnostic information Gastric achlorhydria is common but as already noted normal secretory findings are present in an appreciable number of instances The presence of blood in the gastric contents or in the stools merely demonstrates the existence of an ulcerating or erosive lesion and the degree of anemia indicates the severity of the underlying condition Definite diagnosis must be established by careful roentgenological studies and in dubious cases by thorough examination of the stomach by gastroscopy Once the diagnosis is established or is presumed to be probable radical surgery is indicated The only contraindications to such a maneuver are obvious and advanced metastases or evidence that the patient is a poor operative risk either because of the advanced state of the disease or because of associated conditions Where obstruction to the outlet of the stomach is present gastroenterostomy is a justifiable procedure as a palliative measure Radiation therapy to date has not proved to be of therapeutic value The prognosis of adenocarcinoma of the stomach depends upon two factors The first and of fundamental importance is that of early diagnosis In addition the type of carcinoma as classified pathologically may give a reasonable clue as to the speed of growth and therefore the

Fig 202 —Diffusely spreading carcinoma involving the pyloric portion of the stomach (Herbut s Surgical Pathology )

probability of metastasis In favorable cases, where "doubtful" lesions have been removed surgically long survival rates and apparent cures may be reasonably expected The total number of such satisfactory results is still relatively small Easily diagnosed carcinoma of the stomach has a much poorer prognosis but this fact should not militate against radical surgical procedures

*Scirrhous carcinoma* is characterized by diffuse infiltration and thickening of the wall of the entire stomach, without discrete, easily identified ulceration This type is particularly difficult of diagnosis because it is frequently asymptomatic and may be missed even with careful x ray studies At times it is confused with advanced hyper trophic gastritis

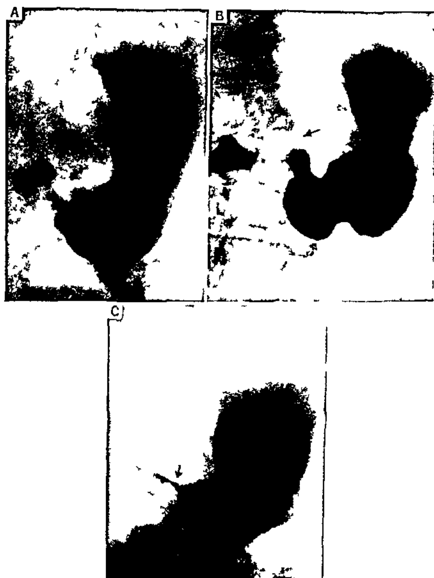

Fig 203 —Roentgenograms showing A spasm of the prepyloric antrum with no organic lesion B early malignant lesion of the prepyloric antrum C late malignant lesion of the prepyloric antrum (Portis Diseases of the Digestive System )

The *tumors of mesenchymal origin* have no distinct clinical characteristics and their detection depends upon the use of the measures outlined above Radiologic examination may indicate clearly that deforming lesions of the stomach are present but ap-

parently arise beneath the mucous membrane thus indicating the source of the growth Ulceration may occur however and the appearance of any of these tumors may be difficult to differentiate from that of carcinoma Occasionally diagnosis may be determined by examination of biopsy material obtained through an operating gastroscope but in most instances a final diagnosis is made only at the time of operation which is always indicated as the proper therapeutic measure

Special reference should be made to the relatively uncommon involvement of the stomach by *lymphoma of the Hodgkin s type* Although rare this disease may involve only the stomach It is characterized by a diffuse infiltration of the major part of the organ The radiological and gastroscopic findings are strongly suggestive of hypertrophic gastritis of an extreme degree with marked distortion of gastric rugae Diagnosis may be made by biopsy material obtained at gastroscopy Symptoms are usually those of an intractable gastritis and when radiologic or gastroscopic findings are difficult to interpret surgical exploration is indicated to obtain adequate biopsy material Identification of the lesion by histological study is important inasmuch as very satisfactory results may be obtained either by total gastrectomy or at times by careful roentgen ray therapy of the stomach itself provided the disease has not involved other areas in the body

# DISEASES OF THE SMALL INTESTINE

Small bowel disturbances may be associated with developmental abnormalities tumors mechanical block by foreign bodies or by torsion intussusception inflammatory or infiltrative diseases or specific infections

## INTESTINAL OBSTRUCTION

With the exception of diffuse inflammatory disease of the small intestine symptoms related to jejunal and ileal abnormalities are essentially those of varying degrees of intestinal obstruction These symptoms consist of crampy peristaltic pain usually localized in the periumbilical area regardless of the level of the disease process In conditions affecting the terminal ileum the symptoms may be referred to the right lower quadrant When there is more than slight obstruction to the passage of intestinal contents at a given point pain is usually accompanied by nausea and vomiting distention high pitched peristaltic sounds that are obviously increased in frequency and intensity above normal and, occasionally local tenderness The greater the degree of obstruction the greater will be the magnitude of symptoms and dehydration and electrolyte loss will be pronounced as a result of prolonged vomiting The vomitus has a fecal odor Films of the abdomen characteristically reveal dilated loops of the small bowel proximal to the obstructed area and these loops frequently show fluid levels

DEVELOPMENTAL ABNORMALITIES consist essentially of diverticula which may be encountered at any level They are rarely the cause of symptoms and when demonstrated accidentally during the course of radiological examination they should be noted and then disregarded unless there is evidence of stasis or bleeding that can be explained in no other fashion

*Meckel s Diverticulum* —One exception to the above rule is the condition known as Meckel s diverticulum This diverticulum is a rather common finding which represents a remnant of the omphalomesenteric duct and is to be found in the ileum at a point approximately 60 to 80 cm above the ileocecal valve Meckel s diverticula frequently contain islands of gastric mucosa and accordingly are associated with the occurrence of ulceration in the ileum opposite or adjacent to the stoma of the pouch In children or young adults this may provide a source of periumbilical pain and bleeding If pain is sufficiently marked it may suggest partial obstruction because of its peristaltic nature Actually partial obstruction may occur due to a local inflammatory process, with swelling and cicatrization Volvulus intussusception and strangulation may also occur and the clinical picture may be that of an acute abdominal emergency It is extremely

rare for the radiologist to be able to demonstrate either the diverticulum or the area of ileum involved unless there is frank obstruction. At times the only finding of importance may be that of anemia, due to blood loss, and careful search may reveal occult blood in the stools. At other times bleeding may be brisk and black or reddish stools may occur in the attacks usually with pain. The condition should always be considered in the presence of otherwise unexplained bleeding from the gastrointestinal tract in younger individuals. The only *treatment is that of surgical resection*.

FOREIGN BODIES may cause local obstruction at any level but the usual site is at or near the ileocecal valve. This obstruction may be due to objects that have been swallowed and have passed the pylorus. One particular form of intestinal obstruction secondary to a foreign body is that caused by a single large gallstone which has perforated through the wall of the gall bladder and has developed a fistulous opening into the duodenum and thence passed into the small intestine. Physical examination may reveal only distention and rather high pitched peristalsis characteristic of obstruction. There may be however a point of local tenderness over the obstructed area which is usually to be found in the right lower quadrant. Roentgenological examination may reveal the presence of a foreign body. Fever and leukocytosis may be present and serious dehydration and loss of electrolytes may occur as a result of persistent vomiting. The condition represents a surgical emergency, and no other form of treatment should be considered. In the case of a gallstone ileus, diagnostic help may be obtained if the history can bring out the fact that the patient has previously suffered from attacks of biliary colic.

VOLVULUS OR INTUSSUSCEPTION.—In addition to obstruction caused by foreign bodies, similar symptoms may occur as a result of volvulus or intussusception. At times, kinking or torsion may be produced without any obvious cause. They may be due, however, to the scars of previous surgery, such as adhesions from a previous appendectomy or from other forms of abdominal surgery. They may also be associated with pelvic disease, causing kinks or torsion of loops of ileum secondary to endometrial implants, carcinoma of the uterus or ovaries, or heavy radiation of the pelvis for malignant disease. A careful history may bring out a record of previous therapeutic measures which may have led to the existing situation.

Intussusception is the invagination of one portion of the intestine into an adjacent segment. In almost every instance, it occurs from above downward. It is most frequently encountered in infants and children. *Precipitating causes include tumors of* all sorts, foreign bodies and Meckel's diverticula, as noted above, and focal areas of inflammatory disease. That portion of the gut which is invaginated into another segment becomes edematous and hyperemic with resulting secretion of excessive amounts of mucus, gross bleeding and, if untreated, necrosis and gangrene.

A further common cause of intestinal obstruction is that associated with inguinal or femoral hernia. Under such circumstances obstructive symptoms may be associated with invagination of a loop or bowel in the hernial sac with kinking, occlusion and possibly with strangulation.

*Treatment*.—In all the situations cited above intestinal obstruction is the presenting difficulty and in most instances surgical intervention is the treatment of choice. If distention is marked, decompression by means of intestinal intubation is of extreme importance as a preliminary measure except where strangulation of the bowel is suspected; in that case immediate surgery is indicated. If decompression is carried out *special attention must be paid to replacement* of fluid and electrolytes which will have been lost by the decompression technique or by previous vomiting. Replacement must be carefully carried out before and after surgery. The exact details of the surgical procedure will depend upon the condition presenting in the abdomen. They may be limited solely to the release of the kinking or torsion, or extreme measures may be required involving resection of areas of gangrenous bowel in advanced cases. Intensive antibiotic treatment may be necessary in individual instances. For the ob

structive symptoms of abdominal pain nausea and vomiting morphine is the drug of choice

## SMALL-BOWEL TUMORS

Small bowel tumors are relatively uncommon They are encountered with much less frequency than are tumors in the stomach or in the colon The *diagnosis* of tumors of the small bowel is made on the basis of symptoms of intestinal obstruction or because of evidences of gastrointestinal tract bleeding Localization of these tumors may be accomplished only by careful radiological studies of the small intestine This is a relatively simple matter as far as the duodenum is concerned When the tumors are located in the jejunum or ileum demonstration of one or more tumors may be extremely difficult and will depend upon the skill of the roentgenologist and the fact that in many instances there is partial occlusion of the lumen of the bowel Where symptoms of obstruction are prominent barium studies may be contraindicated because of the risk of increasing the degree of obstruction but under these circumstances abdominal films may show dilated loops above an area of narrowing If obstructive symptoms are not severe then barium given by mouth may be carefully followed by serial examinations throughout the entire length of the small bowel In a high percentage of cases localization of the lesion causing symptoms may be satisfactorily determined Occasionally tumors may be demonstrated by the passage of a double lumen tube with a balloon attached to one lumen Once the tip of the tube is in the small bowel the balloon may be moderately distended and the tube allowed to pass as far as possible Using this technique it is frequently found that the balloon stops at the partially obstructed area which can then be outlined satisfactorily by introducing barium through the open lumen of the second tube

Benign Tumors —The most common benign tumor of the small bowel is *adenoma* which may exist as a single polypoid tumor or there may be multiple adenomata If pedunculated it may cause intussusception The chief consideration in the treatment of adenomatous polyps aside from that of obstruction, is the potential danger of malignancy *Lipomata* are usually single tend to be pedunculated and are chiefly of importance because of the danger from obstruction or bleeding Other benign tumors are classified as *fibromas hemangiomas myelomas* and *chylangiomas* These are of extreme rarity In the duodenum and upper jejunum small nodular masses of aberrant pancreatic tissue may be found which rarely obstruct but may become ulcerated and produce bleeding Rarely, cysts may occur in the small bowel as a result of congenital malformation

Malignant Tumors —Malignant tumors of the small intestine are relatively uncommon but with improvement in radiologic technique they are being more frequently recognized than formerly Symptoms due to adenocarcinoma sarcoma or carcinoids are no different from those caused by any other partially obstructing or ulcerated and bleeding lesion of the small bowel Of these three tumors *adenocarcinoma* is the most common It occurs most frequently in the mid-duodenum but may be found at any level of the small intestine It may occur as a stenosing annular lesion as an ulcerating infiltrating tumor or in the form of a polyp *Sarcoma* is less frequent and pathologically may be classified as lymphosarcoma the commonest or as leiomyosarcoma fibrosarcoma or neurofibrosarcoma Such tumors as a rule are infiltrating in nature but may ulcerate and may produce obstruction *Carcinoid tumors* (argentaffin tumors) are nearly always found in the appendix or in the region of the ileocecum They are derived from the chromaffin system Although usually benign they may show malignant characteristics with steady growth and with metastases They are usually symptomless unless they are very large or occlude the appendix in such a way as to produce symptoms of appendiceal irritation The adenocarcinomata and the sarcomata have a very poor prognosis because they are relatively asymptomatic for a long time with the result that metastases are frequent If recognized surgical intervention is the only form of therapy to be considered

In general it can be said that in the absence of other symptoms the finding of

anemia with occult blood in the stools always warrants a careful search by radiological studies of the entire small bowel in the hope that a localized tumor may be demonstrated and successfully removed

## INFLAMMATORY DISEASE OF THE SMALL INTESTINE

Inflammatory disease of the small intestine may be due to specific infectious agents such as typhoid or Salmonella infections food poisoning due to specific strains of staphylococci tuberculosis, or to a nonspecific granulomatous process known as regional enteritis Typhoid fever Salmonella infections and staphylococcal food poisoning are discussed elsewhere

*Acute infectious diarrhea* due to infectious agents usually occurs without identification of precise etiology The onset is characterized by anorexia or nausea and vomiting and periumbilical cramplike pains with obvious increase in peristaltic activity and diarrhea Fever may or may not be present At times classified as intestinal grippe at other times designated as food poisoning these episodes are usually short lived, lasting only a few days The onset is abrupt and abdominal pain may be rather severe requiring medication Without marked elevation of temperature or severe prostration and without any history of preceding attacks infectious diarrhea is best treated with immediate rest in bed frequent small feedings of very bland food and avoidance of more than moderate amounts of fruit juice and articles of food containing a large amount of residue Iced drinks should be avoided Fluids should be taken if tolerated preferably in the form of clear hot drinks of broth If there is any real reason to suspect contaminated food as a precipitating cause early purgation with castor oil may be desirable If diarrhea has persisted for many hours or for several days such a measure is to be avoided The use of simple bismuth preparations with or without opium, in the form of paregoric or tincture of opium, may quite adequately control abdominal discomfort and excessive bowel activity Unless there is a striking elevation of temperature, it will be wise to avoid the use of the newer antibiotics such as aureomycin and terramycin inasmuch as these may aggravate the diarrhea and nausea and may in themselves prolong the irritation of the bowel even to the extent of causing bleeding from the lower intestinal tract If the condition comes rapidly under control then a normal diet may be gradually resumed, but it should be remembered that such an infectious episode leaves the entire intestinal tract in a rather irritable condition and failure to avoid excessive roughage may cause a renewal of symptoms If diarrhea persists over any extended period—particularly if there is an associated elevation of temperature then search should be made for specific infectious agents More extensive studies may be indicated It should be particularly emphasized that in infants small children and depleted older people attacks of infectious diarrhea may be very serious due to rapid depletion of fluids and electrolytes Under these circumstances adequate replacement therapy must be provided and failure to do so may occasionally result in a fatal outcome

*Tuberculosis* is discussed in another section but is worthy of brief comment because of the fact that it may be readily confused with regional enteritis The commonest site of intestinal tuberculosis is the lower ileum and cecum The most common form is that of an infiltrating process with superficial ulceration of the ileum In the cecum progressive granulomatous change may occur with marked thickening of the wall and the formation of a tumorlike mass, which may resemble carcinoma The symptoms are those of irritation of the lower small bowel with diarrhea periumbilical or right lower quadrant cramplike pain and the finding of occult blood in the stools Associated with these symptoms there may be loss of appetite and weight with an accompanying anemia Physical examination may reveal a local tender mass in the vicinity of the cecum with evidence of peritoneal irritation as shown by muscle spasm A much less common form of tubercular involvement is *that of local hypertrophic change* with stenosis and gradual obstruction of the terminal ileum In many instances of tubercular enteritis evidences of present or past pul

monary tuberculosis will be found Occasionally it will be impossible to demonstrate the existence of tuberculosis in any other part of the body Rarely the appendix may be involved in the tuberculous process and the presenting symptom may be that of appendiceal pain In the ulcerative form perforation and fistula formation constitute a moderately frequent complication Diagnosis must be based on an adequate history objective physical findings and a careful x ray examination first by barium enema and subsequently by small bowel studies Tubercle bacilli may be found in the stools but this represents an inconstant finding Evidences of tuberculosis elsewhere in the body may provide confirmatory evidence of the disease Because of the location of the lesions the first consideration in differential diagnosis is that of regional enteritis which will be discussed below In the absence of symptoms of obstruction or of fistula formation conservative medical measures with adequate rest a nonirritating diet of low roughage content and antispasmodics should be employed At times tincture of opium and bismuth preparations may be helpful in reducing the number of bowel movements Where the diagnosis is proved streptomycin therapy may be very effective It probably should not be combined with para amino salicylic acid if diarrhea is a marked feature Where obstruction and fistula formation are present surgical resection may be indicated

REGIONAL ENTERITIS —Regional enteritis may be classified as a nonspecific granulomatous disease of the small bowel usually involving one or more segments of the terminal ileum The disease is chronic with remissions and exacerbations and may be entirely asymptomatic the diagnosis being made by accident at the time of abdominal exploration for other disease Pathologically the lesions are those of proliferating granulomata involving primarily the mesenteric border of the small bowel in a single segment or in multiple areas Skip areas are common and in severe cases not only may the jejunum and ileum be involved but occasionally the duodenum as well In a small percentage of cases the disease involves the cecum and the colon in which event the term ileocolitis is usually employed The *etiology* of the disease is not known It bears a close clinical relationship to tuberculosis but it is quite certain that it is not due to this specific infectious agent

The *symptoms* of the disease vary It may be ushered in by an acute febrile attack with the sudden onset of right lower quadrant cramplike pain an elevated temperature and leukocytosis Such an episode is usually mistaken for an acute attack of appendicitis but at operation the characteristic pathological findings of enteritis may be found, in this instance usually well localized to the terminal ileum In other cases the history is that of recurrent episodes of periumbilical or right lower-quadrant cramps with diarrhea slight elevation of temperature and occasionally nausea and vomiting Moderate leukocytosis may be present and the stools may show occult blood *Physical examination* may be entirely negative but almost always reveals right lower-quadrant tenderness some muscle rigidity occasionally rebound tenderness and a palpable mass in the region of the cecum The mass may be easily defined and may be as large as 6 to 7 cm in diameter or it may be distinguished merely as an indeterminate mass characteristic of an inflammatory process Occasionally it is in the low midline rather than in the right lower quadrant In the chronic cases fistula formation may be evident either because of the appearance of the fistula in the abdominal wall or because of the finding of fistulous tracts on subsequent roentgenological examination In the chronic form of the disease appetite may be diminished and the intake of food definitely reduced because of the fear of producing increased diarrhea and abdominal pain Serious loss of weight and severe nutritional disturbances may be encountered The stools are characteristically semi solid rather than liquid containing excessive mucus and on microscopic examination show pus and red cells gross blood may occasionally be present *Differential diagnosis* must include the possibility of ulcerative colitis tuberculous enteritis new growth or in the acute cases acute appendicitis Sigmoidoscopic examination will be essentially negative except for signs of irritation of the rectum and recto

sigmoid, without any evidence of ulcerating lesions Mucopurulent or bloody discharges may be noted coming down from above during sigmoidoscopy A barium enema will frequently show a characteristic and persistent narrowing of the terminal ileum as barium refluxes through the ileocecal valve and produces the so-called "string sign" In most instances the cecum will be normal, but in some cases, cecal involvement may be present, and, as already indicated, there may occasionally be involvement of the remainder of the colon A small-bowel study by *x* ray will demonstrate a permanent deformity or narrowing with irregularity of the normal pattern in the terminal ileum and where the disease is widespread it will usually indicate skip-areas" at higher levels with or without evidences of obstruction If obstruction is present dilated loops of small bowel are always found above the obstructing area Fistulæ may be demonstrable either by barium enema or by small bowel series In the absence of other evidences of tuberculosis, the diagnosis of regional enteritis may be made with reasonable certainty particularly if numerous areas of the ileum are involved

*Treatment* —The treatment of this disease is far from satisfactory It has been reviewed particularly by Crohn and Garlock whose experience with the condition has been extensive Inasmuch as there is no known specific etiological factor medical therapy cannot be said to be in any way definitive The results of surgery are still somewhat controversial In the opinion of the author, conservative measures would seem to be indicated in the absence of proved obstruction or fistula formation and in cases in which symptoms are recent and involvement is limited to a small segment of the ileum Such a conservative attitude may be justified by the fact that, occasionally, completely asymptomatic and apparently healed lesions are found in the course of abdominal exploration for other disease and also by the fact that certain cases seem to have responded well to such conservative measures over a period of many years If medical treatment is to be carried out then the principles of long-continued rest and the administration of a low roughage highly nutritious diet are fundamental considerations Chemotherapy and the use of antibiotics has not been universally successful In some instances a course of sulfadiazine followed by the use of sulfathalidine over a period of weeks or months appears to have been of real benefit Penicillin is of no value Streptomycin may be of help during acute manifestations of the disease and on occasion the use of chloromycetin seems to have

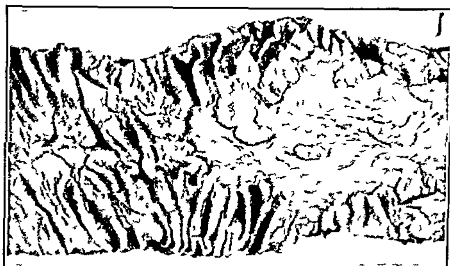

FIG 204 —Regional enteritis illustrating a sharp demarcation between healthy and diseased bowel irregular ulcers and prominent residual islands of mucosa (Herbut s Surgical Pathology )

been followed by beneficial results particularly in the cases with elevated temperature and toxic manifestations. Aureomycin and terramycin are probably contraindicated because of their tendency to cause diarrhea. Mild sedation with the barbiturates and at times the use of atropine or its derivatives are helpful.

Failure to respond to consistent carefully carried-out medical measures undoubtedly should lead to a decision in favor of surgical intervention. The only contraindication to operative interference is the presence of diffuse involvement of the jejunum and ileum which precludes any successful surgical maneuver. In the event that surgical intervention is considered indicated a short-circuiting operation with the performance of an ileotransverse colostomy is the procedure of choice. Combined with this maneuver a resection of the diseased ileum together with the ascending colon may be indicated either because of fistula formation with resulting abscess or because of continuing evidence of disease in that portion of the bowel which was supposed to be put at rest by the short circuit. One of the very real difficulties attending surgery for regional enteritis is the fact that skip areas may evade detection at the time of operation with the result that the disease reappears in active form above the anastomosis. Attempts at radical resection of numerous areas of disease is usually attended by unsatisfactory results. Occasionally local areas of obstruction may require enteroanastomosis for symptomatic relief.

Recurrences may occur either under medical management or after what seems to be properly indicated surgery. Because of the nutritional disturbances that frequently accompany this condition dietary supplements in the form of vitamins and possibly liver extract may be of some benefit. The ultimate prognosis in regional enteritis is never clear in individual cases. In instances in which favorable results are obtained during initial therapy it is of the utmost importance to train the patient in future proper dietary habits as well as in the proper regulation of his life in order to resist the effects of emotional stress and strain, excessive fatigue and intercurrent infection.

## THE SPRUE SYNDROME

Sprue or psilosis is a chronic disturbance of the small bowel characterized by faulty absorption of lipoids and other nutrient elements. The exact etiology of the condition is not known but the response to specific factors such as liver extract, vitamin $B_{12}$ and folic acid, has properly led to the assumption that it is primarily a deficiency disease. The brilliant therapeutic results obtained by Castle and Rhoads following the administration of liver extract and the subsequent demonstration by these authors, Spies and Suarez of the efficacy of vitamin $B_{12}$ and folic acid would certainly point towards such a conclusion. However the fundamental physiologic disturbance exhibited by patients with the sprue syndrome is that of impaired intestinal absorption and it is quite possible that the deficiencies exhibited may be the result rather than the cause of the manifestations of this interesting condition. As partial support for the idea that the syndrome is primarily due to an inherently impaired absorptive function one may cite the fact that it is not at all infrequent to obtain a history from adult patients of earlier nutritional difficulties that have been diagnosed in childhood as celiac disease. For years an attempt has been made to differentiate between cases of so-called tropical sprue occurring in tropical and subtropical areas and cases of sprue encountered in temperate zones which have been classified as nontropical sprue. Such a differentiation is probably an arbitrary one although there is little doubt that the condition is encountered with much greater frequency in the warmer latitudes. Reports by Thayson, Snell, Hanes, Suarez and others would seem to indicate that the syndrome is fundamentally the same wherever encountered although the clinical manifestations may be subject to modification depending upon climate and upon economic and environmental conditions. The identity of tropical sprue, nontropical sprue and celiac disease has been stressed by Hanes and others. The clinical manifestations of this condition and its treatment have been described in Chapter 11. Because the sprue syndrome is fundamentally associated with

impairment of small intestinal absorptive function, it is pertinent to comment briefly on recent therapeutic developments. In cases that have been extremely intractable to the prolonged use of liver extract, vitamin $B_{12}$, and folic acid, dramatic improvement in *intestinal absorption with* subsequent amelioration of all the symptoms of the disease has been achieved by the use of the corticosteroids. Balance studies carried out by this writer and his group, by Wollaeger and by Almy indicate clearly that the use of ACTH or cortisone has been associated with *a striking reduction in the fat content of the* stools, together with disappearance of diarrhea and distention and accompanying evidence of improved general intestinal absorption. It may well be that the use of corticosteroids will provide a valuable addition to our means of controlling this disease in its later stages and, incidentally, serve to increase our understanding of the underlying physiological disturbance.

## APPENDICITIS

Appendicitis is essentially a surgical condition and is the result of an acute inflammatory involvement of the vermiform appendix. It may occur as a single acute attack or may recur at intervals as mild attacks without definite recognition. The *etiology* of the condition would seem to be associated with two factors: fecal stasis with more or less obstruction to the lumen of the tubular *structure,* and infection behind the obstructed area. Infection may be caused by the multiplications of organisms normally contained in the intestinal flora or may be associated with a streptococcal *infection incident* to acute respiratory disease.

*Symptoms.*—The symptoms of appendicitis are classically those of pain, tenderness and spasm in the right lower quadrant. The localization of symptoms may vary, however, with the exact location of the appendix so that both pain and tenderness may be noted in the right flank, in the event that the appendix is retrocecal, or symptoms and signs may be localized in the low mid hypogastrium or in *the pelvis.* At the onset of an attack, the initial symptom is usually that of epigastric pain, with nausea and, possibly, vomiting. As the attack progresses the pain characteristically descends to the right lower quadrant, *and tenderness to palpation* appears at or near a point midway between the iliac crest and the umbilicus (McBurney's point). In an acute attack suggesting the possibility of appendicitis, it is important to remember that tenderness to palpation may be found only by rectal or vaginal examination. In older patients pain may be entirely absent and the condition may be suspected only because of an acute upset with nausea and vomiting and with a subsequent *rise in temperature and local ab*dominal tenderness. The sudden disappearance of pain always suggests perforation of the appendix with a local peritonitis.

*Diagnosis.*—Physical examination, in addition to demonstrating local tenderness, may exhibit rebound tenderness and usually shows muscle rigidity, which is evidence of peritoneal involvement. This is one of the most valuable signs of the condition. Fever is nearly always present; it may be only *moderately elevated or may be between 103* and 104 degrees Fahrenheit. Chills occur infrequently. Leukocytosis is nearly always present with an increase in the polymorphonuclear leukocytes. Except in children where higher counts are to be expected, a white count of over 20,000 cells per cubic millimeter should suggest the possibility of perforation. Differential diagnosis should include consideration of acute cholecystitis, right renal calculus, acute salpingitis, ectopic pregnancy, torsion of an ovarian cyst, ruptured graffian follicle, right lower lobe pneumonia, and acute attacks of gastroenteritis. In older individuals rupture of an *infected diverticulum of the sigmoid,* although usually left sided, may closely resemble an attack of acute appendicitis. In pneumonia of the right lower lobe with pain referred from the diaphragm, the picture may be confusing particularly in children, but, as a rule, one can easily demonstrate that pain is dependent upon respiration and ceases or is almost entirely absent when the patient holds his breath. Furthermore the lack of rebound tenderness or tenderness on rectal examination provides additional information. In the event that perforation of the appendix has occurred, one additional

symptom may be the development of diarrhea which may be the presenting symptom when the patient is seen In this event diagnosis can be made primarily on physical signs alone

*Treatment* —Diagnosis should be made as quickly as possible and should be followed by surgical removal of the appendix Conservative measures and medical treatment rarely are justified It is of extreme importance to avoid the use of laxatives if the diagnosis of appendicitis is *considered possible* and nothing should be given by mouth until the diagnosis is certain In older people or in young children replacement of fluid and electrolytes may be of importance as part of preoperative preparation Where perforation *is suspected with resulting peritonitis* the use of antibiotics particularly penicillin and streptomycin is indicated With prompt diagnosis and treatment the prognosis is good Where the diagnosis has been delayed or where perforation has occurred the outlook depends upon the degree of peritoneal involvement and the measures instituted for its control

*Chronic appendicitis* is a diagnosis that should be avoided since it probably does not exist in any true sense There is little doubt that recurrent attacks of mild appendicitis occur and may eventually be recognized as such But that a truly chronic inflammatory process which is the cause of lower abdominal symptoms occurs is very much to be doubted

## DISEASES OF THE COLON

Disturbances of the colon may be due primarily to abnormalities of motor and secretory function or as in other portions of the digestive tract may be associated with *congenital malformation tumors or inflammatory* disease

### MOTOR AND SECRETORY DISTURBANCES

MUCOUS COLITIS —Excessive *motor and* secretory activity of the large bowel may be appropriately considered under the term mucous colitis or irritable colon The syndrome of mucous colitis consists essentially of gastrointestinal symptoms predominantly referable to the colon It was originally described in a classical article by Da Costa and has subsequently been studied in careful detail by Bockus Friedenwald, White, Jordan and many others

The *symptoms* of this condition are primarily referable to the colon and at one time or another include episodes of constipation or diarrhea accompanied by ab*dominal pain and the passage of stools of* small caliber In the majority of instances the first symptom is that of constipation which typically appears in the second or the third decade Diarrhea is a somewhat later development and may alternate with periods of constipation Characteristically there is a history of the passage of long strings of mucus or of mucous casts of bowel with extreme hypogastric pain In periods of constipation the movements may be hard or soft If hard scybalous masses are passed rectal and anal discomfort may be extreme At times ribbon or pencil like stools are noted indicating increased muscular spasms of the rectal segment and of the anal musculature Pain in most instances is hypogastric and most frequently over the location of the lower descending colon and sigmoid Associated symptoms may include upper abdominal complaints such as heartburn belching epigastric fullness *etc* , and in addition it is common to obtain evidences of autonomic instability such as tachycardia excessive sweating easy fatigability and the like *Lower abdominal pain is* nearly always associated with bowel movements The taking of cathartics almost invariably increases the intensity of the pain as does the ingestion of coarse foods with a high cellulose content A careful history will usually elicit the fact that increased nervous or emotional tension also aggravates symptoms with production of constipation or diarrhea and abdominal discomfort Passage of blood may occur even in the absence of anal fissure or hemorrhoids It is usually noted as streaks of blood on the outside of the stool but may be associated with the passage of larger amounts of red blood although this is a rare occurrence

impairment of small intestinal absorptive *function it is pertinent to comment briefly* on recent therapeutic developments In cases that have been extremely intractable to the prolonged use of liver extract, vitamin $B_{12}$ and folic acid, dramatic improvement in intestinal absorption, with subsequent amelioration of all the symptoms of the disease, has been achieved by the use of the corticosteroids Balance studies carried out by this writer and his group by Wollaeger and by Almy indicate clearly that the use of ACTH or cortisone has been associated with a striking reduction in the fat content of the stools together with disappearance of diarrhea and distention *and accompanying evi*dence of improved general intestinal absorption It may well be that the use of corticosteroids will provide a valuable addition to our means of controlling this disease *in its later stages and, incidentally serve to* increase our understanding of the underlying physiological disturbance

## APPENDICITIS

Appendicitis is essentially a surgical condition and is the result of an acute inflammatory involvement of the vermiform appendix It may occur as a single acute attack or may recur at intervals as mild attacks without definite recognition The *etiology* of the condition would seem to be associated with two factors fecal stasis with more or less obstruction to the lumen of the tubular structure and infection behind the obstructed area Infection may be caused by the multiplications of organisms normally contained in the intestinal flora or may be associated with a streptococcal infection incident to acute respiratory disease

*Chronic appendicitis* is a diagnosis that should be avoided since it probably does not exist in any true sense There is little doubt that recurrent attacks of mild appendicitis occur and may eventually be recognized as such But that a truly chronic inflammatory process which is the cause of lower abdominal symptoms occurs is very much to be doubted

# DISEASES OF THE COLON

Disturbances of the colon may be due primarily to abnormalities of motor and secretory function or, as in other portions of the digestive tract, may be associated with congenital malformation tumors or inflammatory disease

## MOTOR AND SECRETORY DISTURBANCES

Mucous Colitis —Excessive motor and secretory activity of the large bowel may be appropriately considered under the term mucous colitis or irritable colon The syndrome of mucous colitis consists essentially of gastrointestinal symptoms predominantly referable to the colon It was *originally described in a classical article by* Da Costa and has subsequently been studied in careful detail by Bockus Friedenwald, White Jordan and many others

The *symptoms* of this condition are primarily referable to the colon and at one time or another include episodes of constipation or diarrhea accompanied by abdominal pain and the passage of stools of small caliber In the majority of instances the first symptom is that of constipation which typically appears in the second or the third decade Diarrhea is a somewhat later development and may alternate with periods of constipation Characteristically there is a history of the passage of long strings of mucus or of mucous casts of bowel with extreme hypogastric pain In periods of constipation the movements may be hard or soft If hard scybalous masses are passed rectal and anal discomfort may be extreme At times ribbon or pencil like stools are noted indicating increased muscular spasms of the rectal segment and of the anal musculature Pain in most instances is hypogastric and most frequently over the location of the lower descending colon and sigmoid Associated symptoms may include upper abdominal complaints such as heartburn belching epigastric fullness *etc* and in addition it is common to obtain evidences of autonomic instability such as tachycardia excessive sweating easy fatigability and the like Lower abdominal pain is nearly always associated with bowel movements The taking of cathartics almost invariably increases the intensity of the pain as does the ingestion of coarse foods with a high cellulose content A careful history will usually elicit the fact that increased nervous or emotional tension also aggravates symptoms with production of constipation or diarrhea and abdominal discomfort Passage of blood may occur even in the absence of anal fissure or hemorrhoids It is usually noted as streaks of blood on the outside of the stool but may be associated with the passage of larger amounts of red blood although this is a rare occurrence

impairment of small intestinal absorptive function, *it is pertinent to comment briefly* on recent therapeutic developments. In cases that have been extremely intractable to the prolonged use of liver extract, vitamin $B_{12}$, and folic acid, dramatic improvement in intestinal absorption, with subsequent amelioration of all the symptoms of the disease has been achieved by the use of the corticosteroids. Balance studies carried out by this writer and his group, by Wollaeger and by Almy indicate clearly that the use of ACTH or cortisone has been associated with a striking reduction in the fat content of the stools together with disappearance of diarrhea and distention and accompanying evidence of improved general intestinal absorption. It may well be that the use of corticosteroids will provide a valuable addition to our means of controlling this disease in its later stages and, incidentally, serve to increase our understanding of the underlying physiological disturbance.

## APPENDICITIS

Appendicitis is essentially a surgical condition and is the result of an acute inflammatory involvement of the vermiform appendix. It may occur as a single acute attack or may recur at intervals as mild attacks without definite recognition. The *etiology* of the condition would seem to be associated with two factors: *fecal stasis with more or less obstruction to the lumen of the tubular structure and infection behind the obstructed area.* Infection may be caused by the multiplications of organisms normally contained in the intestinal flora or may be associated with a streptococcal infection incident to acute respiratory disease.

*Symptoms.*—The symptoms of appendicitis are classically those of pain, tenderness and spasm in the right lower quadrant. The localization of symptoms may vary, however, with the exact location of the appendix so that both pain and tenderness may be noted in the right flank, in the event that the appendix is *retrocecal*, or symptoms and signs may be localized in the low mid hypogastrium or in the pelvis. At the onset of an attack, the initial symptom is usually that of epigastric pain, with nausea and, possibly vomiting. As the attack progresses, the pain characteristically descends to the right lower quadrant, and tenderness to palpation appears at or near a point midway between the iliac crest and the umbilicus (McBurney's *point*). *In an acute attack suggesting the* possibility of appendicitis it is important to remember that tenderness to palpation may be found only by rectal or vaginal examination. In older patients, pain may be entirely absent and the condition may be suspected only because of an acute upset with nausea and vomiting and with a subsequent rise in temperature and local abdominal tenderness. The sudden disappearance of pain always suggests perforation of the appendix with a local peritonitis.

*Diagnosis.*—Physical examination, in addition to demonstrating local tenderness may exhibit rebound tenderness and usually shows muscle rigidity which is evidence of peritoneal involvement. This is one of the *most valuable signs of the condition.* Fever is nearly always present; it may be only moderately elevated or may be between 103 and 104 degrees Fahrenheit. Chills occur infrequently. Leukocytosis is nearly always present with an increase in the polymorphonuclear leukocytes. Except in children where higher counts are to be expected, a white count of over 20 000 cells per cubic millimeter should suggest the possibility of perforation. Differential diagnosis should include consideration of *acute cholecystitis,* right renal calculus, acute salpingitis, ectopic *pregnancy, torsion of an ovarian cyst,* ruptured graffian follicle, right lower lobe pneumonia and acute attacks of gastroenteritis. In older individuals rupture of an infected diverticulum of the sigmoid, although usually left sided, may closely resemble an attack of acute appendicitis. In pneumonia of the right lower lobe with pain referred from the diaphragm, the picture *may be confusing, particularly in children,* but as a rule one can easily demonstrate that pain is dependent upon respiration and ceases or is almost entirely absent when the patient holds his breath. Furthermore, the lack of rebound tenderness or tenderness on rectal examination provides additional information. In the event that perforation of the appendix has occurred, one additional

as agar or Irish moss may be of extreme help. These preparations should not be used unless at the same time great stress is laid upon the attempt to establish proper bowel habits. When very striking irritation of the bowel is evident on the basis of symptoms or sigmoidoscopic examination preparations of vegetable mucins act as a demulcent and may be employed effectively. For the cramplike pains that at times are extremely severe the use of antispasmodics and of sedatives may be extremely effective. Atropine belladonna or banthine in *tolerance* doses may be employed over variable periods of time and the additional use of the barbiturates in small repeated doses may relieve not only the underlying nervous tension but also the bowel spasm which is a reflection of this tension. Among other important therapeutic details it is of extreme value to plan a program of activity and periodic relaxation that makes it possible to avoid both physical and nervous fatigue. The care of patients with mucous colitis requires endless patience and time but persistent treatment frequently results in alleviation of symptoms and a well-controlled patient.

Atony of the Bowel.—Atony of the bowel may result from various causes. It may be the direct result of an associated peritonitis in which event abdominal distention and the absence of peristaltic sounds and any peristaltic activity will reveal a total lack of intestinal motor function. It is an ominous sign of serious abdominal disease and usually involves both the small and the large bowel. Although the treatment must be primarily directed toward care of the fundamental disorder the distention encountered in the presence of peritoneal irritation may be dramatically reduced by the inhalation of high concentrations of oxygen. Morphine sulphate may also give relief by increasing the tonicity of the gut. Such an atonic distended bowel has no real propulsive activity and in addition serves as a reservoir for important quantities of unabsorbed fluid electrolytes and nutrient material which may further hazard the prognosis of the patient. Therapy must therefore include proper replacement of fluid and electrolytes. Similar atony of the bowel may occur as a result of injury to the spinal cord from trauma or tumor and may also be an accompaniment of syphilitic involvement of the cord. Under such circumstances complete motor activity may not be abolished but normal propulsive movements do not occur and spontaneous evacuation of the bowels becomes extremely difficult. The use of carefully administered saline or oil enemas or of skilfully performed colonic irrigations may be of real assistance in solving the problem until normal bowel activity is at least partially restored. In debilitated individuals particularly those suffering from episodes of severe systemic infections the muscular tone of the bowel frequently becomes diminished. Proper evacuation is retarded both from this cause and as a result of loss of strength in the abdominal musculature which normally provides additional intra abdominal pressure aiding bowel emptying. Such an occurrence is not infrequently seen in instances of poliomyelitis with paralysis of the muscles of the trunk and abdomen. In older individuals who have long suffered from faulty bowel habits and accompanying constipation there may be a gradual loss of colonic tone with slowly progressing distention of the bowel from retained fecal material. Bowel evacuation becomes increasingly difficult and must be aided by the careful use of enemas or of mild cathartics such as cascara or senna or the saline purgatives. Where distention is extreme the use of physostigmine or prostigmine may be temporarily effective. It should be remembered that in this group of older persons fecal impaction of major degree may occur with resulting overdistention of the bowel and the passage of loose watery movements which represent small bowel contents that have slipped past the masses of retained feces. In such instances diarrhea may be the presenting symptom but the cause is properly described as obstipation. Abdominal distention due to dilatation of the large bowel should never be considered as evidence of primary atony of the bowel musculature until a thorough search has been made for a possible cause of colonic obstruction such as an annular carcinoma or diverticulitis.

Almost invariably, certain specific personality characteristics are apparent in patients suffering from this clinical syndrome They are definitely overreactive individuals frequently overconscientious, and highly dependent upon the opinions of others Emotional tension is nearly always an obvious fact and frequently dominates the picture Anxiety guilt, and resentment are the most common emotional states associated with the nervous tension apparent in all these individuals

*Physical examination* usually reveals general nervous excitability with hyperreflexia Not infrequently there are well marked flushing of the skin cold moist extremities and an exaggerated wheal response Almost invariably, the descending colon and upper sigmoid can readily be felt as a firm tubular structure, which is tender to deep palpation Rectal examination may reveal a tight anal sphincter, and hemorrhoids or fissures are not uncommon because of the persistence of constipation or diarrhea Other physical findings of importance are lability of pulse rate and irregular sighing respiration

*Diagnosis* —In addition to a careful history and the demonstration of autonomic-nervous system instability by careful physical examination the most important diagnostic procedure is that of sigmoidoscopy The sigmoidoscopic findings have been most carefully described by Friedenwald and his associates In the early stages of the condition or in the milder cases sigmoidoscopic examination reveals generalized hyperemia and injection of the rectal and rectosigmoidal mucosa with excessive secretion of fresh mucus and extreme irritability to touch Transient spasm may make sigmoidoscopy difficult, but avoidance of a hurried examination will permit the passage of the instrument to its full length In the most severe cases, all these signs are strikingly increased with the excessive production of mucus which is frequently thick and tenacious and is detached from the mucosal surface only with difficulty Careful wiping of the mucosa may reveal very fine granularity but ulceration is not seen Radiological studies are of importance only to exclude other conditions A barium enema may show transient areas of spasm but its chief importance is to demonstrate the absence of signs of ulceration, new growth or diverticulitis The appearance of gross blood in the stools has already been noted Such a finding may occur, but extreme care should be taken to exclude all other possible sources of bleeding before accepting the fact that rectal bleeding may result solely from the hyperemia and increased vascularity typical of this condition

At times the clinical picture of mucous colitis may be closely simulated by true gastrointestinal allergy Although this is a relatively infrequent occurrence a careful allergic history is always indicated

*Treatment* —The condition known as "mucous colitis" or "irritable colon" is extremely common, and because of the severity of the symptoms warrants careful consideration and a carefully planned therapeutic program based on the understanding that all the symptoms are fundamentally associated with an exaggeration of the normal physiological activity of the bowel Once adequate assurance has been obtained that no serious organic disease is present treatment should be directed toward reassurance and the management of the patient as a disturbed, harrassed individual Psychotherapy may at times be of extreme importance, but in many instances, an understanding physician can adequately handle the situation with patience kindness and attention to minor details Sources of anxiety and tension should be searched for fully discussed and, if possible removed or avoided Dietary measures are of importance inasmuch as coarse irritating foods very definitely aggravate symptoms The diet should be chosen with this point in view At times high roughage foods should be entirely avoided or if used should be strained Attention to the regulation of bowel habits is of extreme importance inasmuch as many of these patients are convinced that cathartics are indicated Careful reconstruction of bowel habits is absolutely essential Cathartics should be avoided as well as the use of enemas except in rare instances where the periodic use of an oil retention enema may result in the easier evacuation of hard bowel contents At times the use of mineral oil or of oily combinations with such substances

Physical examination reveals abdominal distention and very often huge fecal masses can be palpated through the abdominal wall. Unless aided by the use of enemas or laxatives bowel movements may occur only at prolonged intervals of many days or weeks. In young children the condition may lead to poor physical development and inadequate nutrition. Abdominal cramps may be present and sometimes though not often nausea and vomiting which are essentially on an obstructive basis. In the milder forms of this disorder fairly adequate bowel activity may be obtained by the use of laxatives or numerous enemas; occasionally physostigmine or prostigmine may be helpful. As the condition develops however surgical intervention may be necessary. Various surgical procedures have been employed including extirpation of the colon and section of the lumbar sympathetic nerves. The recent work of Swenson provides the most hopeful approach to this difficult problem. In a series of patients with congenital megacolon he has found that resection of the lower colonic segment which is poorly supplied with intrinsic nerve fibers and an anastomosis of the distal end of the transected colon to the terminal rectal segment may provide a very satisfactory therapeutic result.

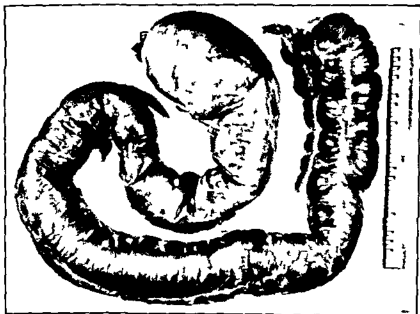

Fig. 205.—Congenital megacolon removed from a boy three years old. (Herbut's Surgical Pathology.)

Diverticulosis.—Diverticulosis of the colon is a very common finding. It probably represents a developmental defect in focal areas particularly in the sigmoid and descending colon with a gradual pouching out of the weakened abdominal musculature until demonstrable diverticula are formed. It is estimated that demonstrable diverticulosis of the colon may be present in 5 per cent of otherwise normal adults. In most instances the condition causes no symptoms, and the diagnosis is made by accident during the course of routine x-ray examination of the gastrointestinal tract. In a moderate number of individuals usually in the middle or later decades of life inflammation of the diverticula may occur and the term *diverticulitis* may appropriately be employed. Such an inflammatory process may occur as a single episode or may be present as a chronic inflammatory process with recurrent symptoms. In an acute episode a definite change in bowel habits occurs which may be marked either by constipation or by diarrhea. It is associated with lower left-quadrant pain and tenderness inasmuch as diverticula located in the sigmoid are most commonly

CONSTIPATION AND DIARRHEA.—Both constipation and diarrhea may occur as symptoms of disturbed motor function that is *entirely independent of structural or organic disease of the bowel.* The term *constipation* should be used to describe a *condition in which bowel activity is retarded* and is accompanied by the passage of hard firmly packed fecal masses. The term *diarrhea should be used to describe a condition in* which there is the passage of frequent, liquid movements. Either condition may be *associated with organic disease or with a* clinical syndrome, such as mucous colitis. However, either condition may be the result *merely of faulty bowel habits, nervous tension,* or endocrine disorders such as hyper- or hypothyroidism, diabetes, pituitary *dysfunction and the like.* Thus hyperthyroidism is commonly associated with increased bowel activity and frequent movements. The movements may be liquid in character or may consist merely in the frequent passage of fairly well formed stools. Myxedema is typically accompanied by sluggish bowel activity with at times rather obstinate constipation. Diabetes, for reasons not fully understood, may be accompanied by the passage of frequent, loose stools. In pernicious anemia and in gastric achlorhydria diarrhea is occasionally an important symptom.

By far the most common cause of constipation is a failure to establish and maintain regular bowel habits. This is a most important point to be emphasized inasmuch as the use of cathartics in such instances is usually not indicated and the condition can be corrected by persistent attempts to regulate the hours of eating, the taking of an adequate amount of fluid, and the establishment of an invariable and regular time for going to the toilet. Where constipation is of long standing the use of oily *preparations or of* mild cathartics may help to initiate bowel movements at a given time of day, but the continued use of these *preparations* is to be discouraged.

Diarrhea may occur merely as the reflection of a good deal of nervous and emotional tension. The characteristic of this type of diarrhea is that almost invariably the bowel movements occur only in the waking hours. As a rule the movements come in the morning before and after breakfast and again after the intake of food at other times during the day. Loss of weight and malnutrition are rarely present even *though bowel movements may* occur as many as eight to ten times during the day. The condition is aggravated by excitement, emotional tension, and frequently by the use of iced drinks, excessive amounts of alcohol and coarse foods. In addition to attempts to modify the emotional tension *that is* present, therapeutic measures may properly include the use of small repeated doses of tincture of opium with or without *tolerance doses of belladonna* in order temporarily to slow down bowel activity and diminish bowel irritability. Where nervous *diarrhea is of long standing these drugs may* properly be employed over a period of many weeks in order to break into what is essentially a *vicious cycle.*

## CONGENITAL ABNORMALITIES

Congenital abnormalities of the colon present two widely divergent conditions: megacolon and diverticulosis.

MEGACOLON (HIRSHSPRUNG'S DISEASE).—This condition is usually found in children and presents a remarkable and extreme dilatation of the large bowel. The dilatation may extend to the internal sphincter of the anus but more commonly ends at a slightly higher level. The mechanism underlying this condition is not completely clear, but recent investigations by Swenson indicate that in a large proportion of cases there is a distinct abnormality of the intrinsic innervation of the bowel wall just proximal to a *terminal segment which is quite normal.* This abnormality consists in the absence of Auerbach's plexus in the rectosigmoid. As a *result of this faulty innervation of the lower colon, propulsive movements are* ineffective or absent, with resulting failure to move material from the upper levels of the bowel downward through the distal segment into the anal canal. As a result the child or young adult provides a history of steadily increasing difficulty in bowel evacuation with increasing abdominal distention due to the dilatation of the entire colon

but when it is encountered it may be profuse and sufficient in degree to produce serious blood loss. A definitive diagnosis must depend upon careful radiological studies by barium enema. In most instances no difficulty is encountered in establishing the presence of diverticula and the existence of associated spasm when an inflammatory process is present. Occasionally the deformity and the narrowing of the sigmoid colon cannot be distinguished from an infiltrating malignant lesion.

*Treatment* in the milder cases consists in the use of proper dietary measures, antispasmodics and morphine for the control of pain and soothing retention enemas. In relatively acute cases the diet must consist entirely of foods with small residue. Atropine or its derivatives in therapeutic doses may be of additional help in relaxing a certain amount of spasm and in relieving cramplike pains. Where pain is severe morphine is indicated. Chemotherapeutic agents are probably of little help unless there is evidence of a peritonitis associated with perforation. In an acute or subacute attack the use of small hot (115–120 degrees Fahrenheit) oil retention enemas may provide striking symptomatic relief. Cathartics and laxatives are contraindicated. In the very acute attack that suggests perforation with peritoneal involvement surgical intervention is necessary. Where obstructive symptoms are marked and of long duration or attacks occur with increasing frequency, resection of the involved area of the bowel must be carried out. Furthermore if it is suspected that the lesion may be malignant, a similar procedure is mandatory. In patients with recurrent mild symptoms adequate control may be obtained by low roughage diets, the use of small frequent doses of mineral oil and at times the use of antispasmodic drugs.

## TUMORS

About a third of all the tumors occurring in the gastrointestinal tract are to be found in the colon. Somewhat more than half of these represent benign conditions but malignant tumors of the large bowel are among the most frequent tumors in the body.

Benign Tumors.—The most common benign tumors of the large bowel are adenomata and lipomata. Adenomata may occur as single tumors in any part of the large intestine. They may be multiple occasionally; they are present as a diffuse generalized polyposis of the entire colon. The adenomas appear as polypoid masses which are pedunculated or sessile. The pedunculated tumors may have a rather long vascular stalk and when located in the region of the sigmoid may produce symptoms of obstruction. Adenomata may occur in the earlier decades of life or may be acquired in the later decades of life, possibly secondary to chronic inflammatory disease. All adenomatous polyps are potentially malignant. Where there is generalized polyposis of the entire bowel there is frequently a familial incidence of the condition. When such a case is encountered it is advisable to examine the siblings of the patient and possibly other members of the family inasmuch as the condition is always associated with carcinomatous degeneration. Lipomata as well as the less common fibromata, myelomata and hemangiomata may also appear as polypoid masses, either sessile or pedunculated.

*Symptoms.*—The symptoms caused by any of these benign tumors are due to bleeding or to interference with normal bowel activity as a result of partial obstruction or intussusception. Hemorrhage from benign tumors of the bowel is common and may occur without any other symptom. Recurrent attacks of lower abdominal cramping pain with diarrhea or constipation are frequent and evidences of bleeding nearly always accompany such disturbances. Progressive anemia may be present and where malignant degeneration has occurred loss of weight and strength are accompanying features.

*Diagnosis.*—The diagnosis of benign tumors is based on the history of bleeding, on episodes of lower abdominal pain and on adequate sigmoidoscopic and radiological studies. If anemia is practically the only presenting sign and occult blood in the stools has been demonstrated sigmoidoscopy and examination of the colon by barium enema are essential measures. Very fre-

involved in an inflammatory process Physical examination—or rectal examination if a lower segment is affected—will reveal a tender mass in the left lower quadrant over the course of the sigmoid In milder cases, the symptoms may be less striking and may be initiated by gross indiscretions in diet by lack of regulation of bowel habits, by extreme fatigue or nervous tension with resulting changes in bowel activity or by intercurrent infection In any event the pain or discomfort is characteristically located over the course of the involved bowel and *physical signs* are as described above When spasm of the sigmoid is extreme because of the local inflammatory process which may include tremendous thickening and edema of the bowel wall, the symptoms and signs may be those of large bowel obstruction Fever and leukocytosis may be present In very acute attacks, perforation of a diverticulum with the formation of a pelvic abscess, may occur Such attacks at times simulate acute appendicitis, although in most instances the pain and tenderness is on the left Fistula formation may develop between the sigmoid and the urinary bladder In milder cases bladder symptoms are not infrequent, and, at times, the patient complains primarily of bladder irritability and frequency of micturition

FIG 206 —Diverticula of the colon demonstrated by a barium enema Note the bud like projections as indicated by the arrows (Holmes and Robbins Roentgen Interpretation )

In most instances the *diagnosis* can be made by careful history and physical examination but in every instance the physician must rule out the possibility of carcinoma The coexistence of carcinoma of the sigmoid and diverticulitis is not rare It is probable however that chronic diverticulitis *per se* does not lead to the development of malignant degeneration Bleeding rarely occurs

fluid material frequently mixed with blood There may be an alternation of diarrhea and constipation Profound anemia is a characteristic finding in tumors of the right side of the colon, probably due to the fact that diagnosis is more frequently deferred because of the absence of obstructive symptoms In the descending colon the rectosigmoid and the rectum obstructive symptoms are common and consist in increasing difficulty in evacuation of the bowels lower left abdominal cramping pains distention and the passage of fresh blood and mucus in the stools Loss of appetite is frequent and nausea and vomiting are common accompaniments of left sided cancer

Physical examination usually reveals evidence of anemia and loss of weight Abdominal distention is not uncommon and, in a large percentage of cases a palpable tumor mass may be felt either by abdominal palpation or by digital examination of the rectum Too great emphasis cannot be placed on the fact that the vast majority of rectal cancers can be felt with the examining finger There is no reasonable excuse for failing to make a careful digital examination on any patient complaining of the passage of fresh blood in the stools

*Diagnosis* of malignant disease of the colon is usually easy If rectal examination does not readily disclose a tumor sigmoidoscopy should be performed before radiological studies are made By means of sigmoidoscopy, a tumor may be demonstrable within the range of the instrument but beyond the reach of the examining finger If no tumor is seen it may nevertheless be possible to observe bloody material coming down to the mouth of the scope which indicates an ulcerating lesion at a higher level If digital and sigmoidoscopic examinations are negative then a barium enema should be given for a study of the higher levels of the large bowel In most instances little difficulty will be encountered in localizing the deforming lesion Occasionally in the presence of partial obstruction radiological study may

Fig 208 —Cancer of sigmoid Note irregular area of stenosis with shelf like appearance above and below narrowed portion of bowel

quently single sessile or pedunculated polyps may be seen just at the upper limit of sigmoidoscopic examination. They may be beyond the reach of the instrument, however, and are then to be searched for by means of a barium enema. Occasionally, they can be demonstrated only by so called double-contrast enemas.

*Treatment.*—Treatment of benign tumors of the colon is surgical. Although there is no exact knowledge of the percentage of malignant degeneration of benign polyps, the only reasonable course is to insist upon removal whenever polyps or other benign tumors are demonstrated, either by local fulgeration through a sigmoidoscope when the tumors are limited to the rectum or by actual excision or resection of the affected bowel area, when the tumors are found at higher levels. At the present time total colectomy would seem to be the only reasonable procedure in the treatment of generalized polyposis.

MALIGNANT TUMORS.—With few exceptions malignant tumors of the colon are carcinomatous. Infrequently, colonic malignancy may be on the basis of sarcomatous infiltration, usually classified as lymphosarcomatous. More than half of all carcinomata of the large bowel are to be found in the rectum and rectosigmoid. Carcinomatous tumors may be present as large, ulcerating cauliflowerlike masses, or may be annular in type, with partial or almost complete obstruction of the lumen of the bowel. A third type, colloid carcinoma, is characterized by a large tumor mass with abnormal production of mucinous material. The colloid form of carcinoma is most frequently found in the region of the cecum or the right colon. The scirrhous type of carcinoma occurs most commonly in the rectum and rectosigmoid.

FIG. 207.—Cancer of cecum. Note irregular moth eaten appearance of involved area.

*Symptoms.*—There is a striking difference between the symptoms of malignancy in the right half of the colon and that encountered in the left portion of the bowel. Obstructive symptoms are usually lacking in cecal or right-colonic malignancy. Diarrhea is common, with the passage of large amounts of

be fatal in a few weeks without the convincing demonstration of any pathogenic organism. Persistent ulcerative colitis may be associated with chronic amebic dysentery but may persist after all evidences of amebic infestation have disappeared with successful antiamebic therapy. A point worthy of note is that the vast majority of individuals suffering from idiopathic ulcerative colitis are essentially overreactive, immature, highly dependent and insecure. Indeed at times the psychological aspects of the condition may be dominant and cumulative emotional disturbances may appear to have precipitated the condition. Until definitive proof is obtained of a single specific etiological factor, it is wise to consider nonspecific ulcerative colitis as a condition which is the result of varying types of insult to the bowel occurring in individuals who are peculiarly unstable from the psychological point of view.

In typical cases the pathological process involves first the rectum and rectosigmoid and subsequently, the remainder of the colon up to the ileocecal valve. In a small percentage of cases the disease may be characterized by a regional distribution of the lesions in either the ascending or the transverse colon, but in such instances there is no assurance that the disease will not progress downward toward the rectum. Involvement of the terminal ileum does occur but in relatively few cases. A point of confusion is due to the fact that some cases of regional enteritis involve not only the terminal ileum but also the colon and run a course almost identical to that of typical ulcerative colitis. The initial lesions of the disease are usually readily seen on sigmoidoscopic examination and are characterized by the presence of minute superficial bleeding points throughout the mucosal surface with hyperemia, swelling and great friability. In this stage of the disease the diagnosis may frequently be missed if the mucosal surface is not carefully wiped during sigmoidoscopy, inasmuch as it is common to find a layer of shiny mucus overlying the entire area and giving it the appearance of an almost normal rectal or rectosigmoidal surface. Invariably gentle wiping with a sponge will reveal the lesions described above and a finely granular irregular surface. At this stage the lumen of the rectum or rectosigmoid may be of normal size but it is always extremely irritable and exhibits spasmodic contraction to contact. Occasionally, the process is limited for years to the rectum alone or to the rectum and lowest segment of the rectosigmoid but it must be remembered that the situation may change abruptly from one of apparently superficial localized disease to a diffuse fulminating process involving the entire colon. As the disease progresses, sigmoidoscopic examination reveals narrowing of the lumen of the bowel with marked edema and stiffness. Granularity becomes coarser and superficial ulcers ranging from 0.5 to 2.0—3.0 mm. in diameter may be seen. Serpiginous ulcers are sometimes encountered and when noted, should raise the question of tuberculous involvement. In the late stages of the disease involvement of the entire colon occurs with eventual ulcerative denudation of the mucosa and fibrous thickening from scar tissue. At this point x-ray examination of the bowel reveals so-called pseudopolyps which in most instances are composed of small areas of fibrous tissue or remnants of mucosa. Eventually the entire bowel becomes a thickened fibrous tube of small caliber. In the very acute stages of the disease tremendous thickening of the bowel wall may occur, equivalent to a phlegmonous cellulitis.

Perforation of ulcers fortunately is not common, but it may occur at any time in the very active stages of the disease leading to local abscess formation, peritonitis or fistulous tracts communicating with the abdominal wall, the small bowel or the vagina. Other immediate complications of the disease are the development of anal fissures, hemorrhoids, perianal abscesses, periurethral abscesses and osteomyelitis of the sacrum or coccyx.

Other more distant complications of the disease are the development of various deficiencies, joint manifestations, the appearance of cutaneous lesions, clubbing of the fingers and hepatic changes. Evidences of deficiency disease range from the typical manifestations of the various avitaminoses to profound dehydration, electrolyte im-

reveal only a narrow area beyond which barium does not pass. This in itself gives sufficient evidence of the location of the disease, but confirmation may often be obtained by an abdominal film which may show a distended bowel full of feces and gas above an obviously narrowed segment. If the tumor can be reached by sigmoidoscopy a biopsy can readily be taken by careful curettage, permitting adequate histological examination of the specimen. It is important to mention that, at times, tumors obstructing the rectum or rectosigmoid may arise from structures in the pelvis or may even represent gravity metastases from upper abdominal neoplasms. In this event sigmoidoscopy and radiological studies will merely reveal evidences of pressure external to the lumen of the bowel. A note of warning should be given regarding the danger of radiological examination by means of a barium meal in the presence of obstructing lesions of the colon.

The localization of pain due to neoplasm of the bowels is, in most instances, in the hypogastrium, and this point can be verified by careful history. At times, however, upper abdominal discomfort or pain may be present, particularly if the lesions are near the hepatic or splenic flexures or are in the transverse colon or if extreme distention of the ascending and transverse colon is present because of obstruction at a lower level. This interpretation of the history may lead to the giving of barium by mouth in a search for gastric or small bowel disease. If the narrowing of the colon is marked, serious obstructing symptoms may be precipitated by the giving of a barium meal which may not only complicate the immediate situation but render proper surgical measures difficult and more dangerous. It is essential, therefore, that a very adequate interpretation of the history be obtained before orders are given for radiological studies.

*Treatment.*—The treatment of malignant disease of the large bowel must of necessity be surgical. The results of rectal and colonic surgery for neoplasm are very much better than those obtained following operation for neoplasm of the upper digestive tract. Reports of five year cures suggest that 20 or 30 per cent of the resections are successful. The number of resectable tumors, even when palpable masses are present, is probably better than 50 per cent. Careful preoperative preparation is highly essential, and in right-sided colonic malignancy, treatment of the accompanying anemia is absolutely necessary. It goes without saying that an early diagnosis is desirable. In this connection, it is important to point out that apparently benign polypoid lesions are all too frequently neglected in the hope that they may not undergo malignant degeneration. Such a course is unjustifiable and frequently leads to the development of inoperable cancer.

## ACUTE INFLAMMATORY DISEASE ULCERATIVE COLITIS

Acute inflammatory disease of the colon may be due to infectious agents, as in the case of bacillary dysentery, *Salmonella*, typhoid, and other enteric infections. More chronic forms of ulcerative disease of the colon may be due to specific causes such as tuberculosis, amebiasis and schistosomiasis. These conditions are fully described in other sections. Aside from these disease entities ulcerative colitis may occur as a chronic, progressive disease without known etiology. It is characterized by remissions and relapses in most instances. Typically, it is first encountered in the second and third decades of life, but it may occur in young children or in aged persons. Although primarily a disease of young adults, there is no predominant sex or racial distribution. The onset of the disease is usually insidious, but the condition may be ushered in by an acute attack of fever, nausea and vomiting, and diarrhea. Occasionally, the early symptoms are those of constipation, with the passage of blood and mucus on the outside of formed stools. Although intensive studies have been carried out in an attempt to identify the causative factors, no proof exists that the condition is caused solely, or even usually, by any single infectious agent. Attacks may apparently be precipitated by such diverse conditions as bacillary dysentery, Salmonella infection, measles and episodes of so called intestinal grippe or other virus like diseases. The initial attack may be violent and may

sick individuals oral intake will be entirely inadequate and parenteral feeding necessary but every effort should be made to encourage the patient to take adequate amounts of food by mouth The pain or cramplike discomfort that is frequently associated with active diarrhea may be alleviated by preparations of opium and/or atropine but great care must be observed to avoid overdistention of the bowel by the use of such drugs Except in mild cases the use of bismuth preparations or mixtures of kaolin and vegetable mucin is extremely ineffective The use of chemotherapeutic agents and antibiotics will be attended with varying success No one of the sulfonamides can be used with predictable effect and the same holds true for the newer antibiotics In cases with an elevated temperature striking benefit may be obtained at times with a very adequate dosage of sulfadiazine but generous amounts of fluid must be administered to avoid renal complications If sulfadiazine is effective it may be proper to change subsequently to sulfathalidine or sulfasuxidine for use over *periods of several weeks or even longer* Penicillin is rarely of any value Chloramphenicol has been of benefit in some cases and very occasionally aureomycin has seemed to be helpful The latter drug should be used with caution however because of its tendency to produce nausea vomiting and diarrhea Streptomycin rarely is of benefit In general it can be said that the use of antibacterial agents may at times be an important part of the treatment but they can rarely be depended upon to do more than control immediate urgent situations

Attempts have been made to explain the manifestations of ulcerative colitis on an allergic basis As a primary etiological factor allergic disturbances are undoubtedly of rare and dubious significance Food allergy may exist and this should be taken into account in planning dietary management This is particularly true in the presence of active disease where food allergens may be more readily absorbed through a damaged mucosa with subsequent aggravation of symptoms or skin manifestations At best allergic disturbances are of contributory rather than of primary etiological importance

Because of the manifestations of joint involvement erythema nodosum *etc* it has been logical to attempt to treat patients with ulcerative colitis with ACTH or cortisone Experience with these preparations is still too recent to permit proper evaluation It would appear however that striking temporary remissions may be obtained in cases in which there is relatively superficial involvement of the bowel but marked activity of the disease (as evidenced by bloody diarrhea fever and toxic manifestations) Where marked structural changes have occurred in the colon relatively little or no beneficial effect is to be expected The corticosteroids should be used with great caution but it is highly probable that these or similar drugs may provide a very significant addition to our means of therapy They should never be used unless the patient is under close hospital observation

Mention has already been made of the profound emotional disturbances that are *rather characteristic of the disease This* particular phase of the subject is a highly controversial one but there can be no doubt that carefully planned psychotherapeutic measures when combined with good medical care may be of extraordinary help in getting the disease under control Under no circumstances should the treatment of the patient be carried out without full realization that the individual as well as the disease must be successfully managed It should also be recognized that unskilful psychotherapy may precipitate critical situations with extreme suddenness

One special consideration is worthy of mention namely the question of pregnancy in patients with ulcerative colitis Experience has generally shown that planned pregnancy if the women are really desirous of having children can usually be managed successfully without detriment to the patient or any aggravation of the colitis although the immediate postpartum period must be watched with extreme care On the other hand unexpected and undesired pregnancies in ulcerative-colitis patients are almost always attended by serious exacerbations of the disease

balance and clinical tetany associated with a lowered serum calcium Joint changes may occur during active exacerbations of the disease independently of symptoms referable to the colon Occasionally they precede the development of typical ulcerative colitis They are encountered in at least 10 per cent of the cases and can in no way be distinguished from the manifestations of typical rheumatoid arthritis Any or all of the joints of the body may be involved and the condition may prove particularly intractable unless the underlying chronic disease can be very adequately controlled Skin manifestations in general are of three types Erythema nodosum occurs with relative frequency Pustular lesions involving different skin areas may be noted and may require local surgical drainage A very distressing but rare manifestation is the appearance of large superficial sloughing lesions over the lower extremities with crusting or eschar formation These lesions have the appearance of those due to symbiotic bacterial invasion but positive cultures are never obtained Very occasionally, very serious uveitis or keratitis is encountered Such a complication is a very serious one and closely resembles that occasionally seen in rheumatic infection Enlargement of the liver, due to underlying fatty changes, is not uncommon Degenerative changes in the liver sometimes occur with necrosis of parenchymal cells subsequent fibrosis, and the development of a cirrhotic process Pylephlebitis or multiple liver abscesses are sometimes encountered too Another rare manifestation is bacterial endocarditis due to enteric organisms Renal calculi (uric acid) are occasionally the cause of complicating symptoms Indeed it may be said that, during the course of ulcerative colitis the entire spectrum of many of the most important manifestations of internal medicine may be encountered

Fig 209 —Chronic ulcerative colitis The wall is thick and fibrotic and the mucosa is ulcerated and covered with pseudopolyps (Herbut s Surgical Pathology )

*Treatment* —The successful treatment of ulcerative colitis requires a profound knowledge of the science of medicine and endless patience and watchfulness General supportive measures in the presence of serious diarrhea are always of fundamental importance Rest reassurance and at times sedation are of great help Replacement of fluid electrolytes whole blood and vitamins must be carefully carried out whenever needed Dietary measures require that the food intake be adequate in calories and protein and low in roughage In extremely

sick individuals oral intake will be entirely inadequate and parenteral feeding necessary but every effort should be made to encourage the patient to take adequate amounts of food by mouth The pain or cramplike discomfort that is frequently associated with active diarrhea may be alleviated by preparations of opium and/or atropine, but great care must be observed to avoid overdistention of the bowel by the use of such drugs Except in mild cases the use of bismuth preparations or mixtures of kaolin and vegetable mucin is extremely ineffective The use of chemotherapeutic agents and antibiotics will be attended with varying success No one of the sulfonamides can be used with predictable effect and the same holds true for the newer antibiotics In cases with an elevated temperature striking benefit may be obtained at times with a very adequate dosage of sulfadiazine, but generous amounts of fluid must be administered to avoid renal complications If sulfadiazine is effective it may be proper to change subsequently to sulfathalidine or sulfasuxidine for use over periods of several weeks or even longer Penicillin is rarely of any value Chloramphenicol has been of benefit in some cases and very occasionally aureomycin has seemed to be helpful The latter drug should be used with caution however, because of its tendency to produce nausea vomiting and diarrhea Streptomycin rarely is of benefit In general it can be said that the use of antibacterial agents may, at times be an important part of the treatment but they can rarely be depended upon to do more than control immediate urgent situations

Attempts have been made to explain the manifestations of ulcerative colitis on an allergic basis As a primary etiological factor allergic disturbances are undoubtedly of rare and dubious significance Food allergy may exist and this should be taken into account in planning dietary management This is particularly true in the presence of active disease where food allergens may be more readily absorbed through a damaged mucosa with subsequent aggravation of symptoms or skin manifestations At best allergic disturbances are of contributory rather than of primary etiological importance

Because of the manifestations of joint involvement erythema nodosum *etc* it has been logical to attempt to treat patients with ulcerative colitis with ACTH or cortisone Experience with these preparations is still too recent to permit proper evaluation It would appear however that striking temporary remissions may be obtained in cases in which there is relatively superficial involvement of the bowel but marked activity of the disease (as evidenced by bloody diarrhea fever and toxic manifestations) Where marked structural changes have occurred in the colon relatively little or no beneficial effect is to be expected The corticosteroids should be used with great caution but it is highly probable that these or similar drugs may provide a very significant addition to our means of therapy They should never be used unless the patient is under close hospital observation

Mention has already been made of the profound emotional disturbances that are rather characteristic of the disease This particular phase of the subject is a highly controversial one but there can be no doubt that carefully planned psychotherapeutic measures when combined with good medical care may be of extraordinary help in getting the disease under control Under no circumstances should the treatment of the patient be carried out without full realization that the individual as well as the disease must be successfully managed It should also be recognized that unskilful psychotherapy may precipitate critical situations with extreme suddenness

One special consideration is worthy of mention namely the question of pregnancy in patients with ulcerative colitis Experience has generally shown that planned pregnancy if the women are really desirous of having children can usually be managed successfully without detriment to the patient or any aggravation of the colitis although the immediate postpartum period must be watched with extreme care On the other hand unexpected and undesired pregnancies in ulcerative-colitis patients are almost always attended by serious exacerbations of the disease

Surgical interference may be necessary at any time in the course of the disease, either to save life, to render the patient a useful individual, or ultimately to provide a complete cure of the condition. Ileostomy is the only proper initial procedure. In fulminating cases, ileostomy as a life-saving procedure is very disappointing and the risk may be greater than that of conservative treatment. Except for the very acute, violent manifestations of the disease, ileostomy as a life saving procedure usually implies that the physician has waited too long before calling for surgical help. A proper attitude toward ileostomy is as follows: when the patient ceases to be reasonably active because of his disease, ileostomy should be performed as an elective measure. The newer mechanical devices at present available, skilful care of the operative site and the early employment of sealed collecting bags have appreciably reduced the handicaps of ileostomy life. Total colectomy after ileostomy may be indicated and should be performed if diarrhea or bleeding persists or if acute exacerbations of the disease recur. In disease of long standing, either before or after ileostomy, the danger of carcinomatous change in the colon should not be overlooked. The incidence of cancer in chronic cases of this disease is undoubtedly higher than in the general population, and the careful physician should constantly bear this in mind in planning adequate supervision of his patient. An additional indication for ileostomy is the presence of intractable perianal sepsis, recto-vaginal fistulæ, eye complications or crippling joint manifestations. Acute perforation of the bowel obviously demands surgical intervention.

# DISEASES OF THE LIVER

## GENERAL CONSIDERATIONS

An adequate understanding of hepatic disease must include a reasonable knowledge of liver anatomy and function. Structurally the liver is composed of parenchymal (polygonal) cells, reticulo-endothelial cells (Kupffer cells), sinusoids, biliary canaliculi and ducts, stroma, and vascular elements. Hepatic disease may involve primarily any of these anatomical structures. Thus toxic or infectious agents may damage the parenchymal cells, thereby interfering with anabolic and catabolic processes essential to the body economy. External interference *with the ductal system may produce back* pressure into the bile canaliculi, with resulting bile stasis and cholangitis. Generalized disease of the reticuloendothelial system may involve these elements in the liver, or they may be affected directly by infectious agents or particulate matter. Disease of the portal system or trauma to the hepatic artery or its radicles may reduce the blood supply of the liver to an important degree. Congestive heart failure or pressure on the hepatic veins may prevent adequate venous return from the organ, with resulting venous stasis, swelling and tissue anoxia. In the early stages of any given disease any one of these elements may be solely affected. As the disease process progresses, all the structural elements may become involved, either in a diffuse necrotizing process or in the changes that accompany repair and scar tissue formation. On the basis of our present knowledge it is not possible to state that serious damage to the reticulo-endothelial system is necessarily fatal. Extensive damage to the parenchymal cells with destruction of a large number of these functional elements will invariably result in varying degrees of hepatic failure, which may lead to coma and a fatal outcome. Any consideration of the results of damage to the liver should include a thorough realization of the fact that the organ possesses tremendous powers of repair in the face of extensive damage. Indeed it can be said that immediate survival after serious liver injury will depend upon the adequacy of the repair process in relation to the amount of parenchymal tissue destroyed, regardless of architectural changes. In the more chronic forms of liver disease *compensation to structural damage* will depend upon the degree of regeneration of functional elements. The ultimate prognosis and the degree of useful activity that may be acquired in the presence of permanent liver damage will eventually depend upon the actual mass of functioning parenchymal cells. Therapy, therefore, *must be* continuously directed toward those measures

which spare the liver encourage cellular regeneration and replace temporarily or permanently damaged hepatic functions

The functions of the liver are numerous and by no means thoroughly understood In general they can be grouped under three headings (1) excretory (2) metabolic, and (3) detoxifying or bacteriocidal Normal excretory function may be said to involve the elimination or passage of such substances as bilirubin bile acids alkaline phosphatase foreign substances such as aniline dyes and cholesterol Metabolic processes include gluconeogenesis glycolysis deamination of amino acids and other aspects of protein *metabolism phospholipid metabolism* fat transport fibrinogen formation prothrombin formation the formation of vitamin A from carotene and numerous other intricate biochemical processes The liver is the sole source of bile acids and one of its most important functions is the maintenance of optimum levels of albumin in the blood In addition to the formation of fibrinogen hepatic function undoubtedly includes an active participation in the combining of heme and globin It also contributes a factor necessary for the proper maturation of the red cells The parenchymal cells and the reticulo-endothelial cells are undoubtedly concerned with bacteriolysis and immunological processes and the detoxification or conjugation of various poisonous substances such as belladonna alkaloids morphine and the like In some imperfectly understood fashion the liver also is undoubtedly concerned with the conjugation of steroids and hepatic failure is at times accompanied by clinical manifestations of estrogen or androgen imbalance

Attempts to measure abnormalities in any of the above mentioned hepatic functions are only partially successful In many instances quantitative deviations from normal behavior may be demonstrated In others only qualitative changes may be shown Of some aspects of liver function our knowledge is still so vague as to enable u merely to guess at the nature and the degree of the underlying disturbance At best liver function tests must represent imperfect and rather crude attempts to estimate functional abnormalities It should never be forgotten that a very large degree of damage must be present before any of the tests measuring hepatic function show evidences of abnormal behavior This is particularly true in relation to those tests which attempt to measure parenchymal-cell function In the clinical use of liver function tests it is to be emphasized that the results of such examination are not usually diagnostic although they occasionally give reasonably exact information For the most part diagnoses are made on the basis of clinical skill and confirmation is obtained by laboratory measures On the other hand it is also important to recognize that the progress of *a given disease of the liver may be followed* with much greater accuracy by the careful use of selected tests of liver function than in any other manner

Specific liver function tests warrant brief and somewhat general consideration The detailed techniques of individual tests will be found in original articles Tests of excretory function include simple examination of the urine and stools for the presence or absence of bile pigments Thus in cases of obstructive lesions the urine will contain excessive amounts of bilirubin and the stools will contain little or none of this pigment depending upon the degree of obstruction Where obstruction is great stool and urinary urobilinogen will be markedly diminished In complete obstruction of the external biliary passages the stool will be completely clay-colored and will contain no bilirubin or urobilinogen (except in rare instances) and the urine will be free of urobilinogen Typically in cases of obstruction, the blood serum contains increased amounts of bilirubin and at the same time yields high values for alkaline phosphatase and in many instances total cholesterol The highest values of alkaline phosphatase and cholesterol in the serum will be encountered in cases of complete obstruction due to neoplasm or in those unusual cases of cholangiolitis with a high degree of intracanalicular block Any degree of biliary obstruction either internal or external will show increased retention of bromsulphalein in the blood serum Exclusion of bile from the duodenum results in a short time in faulty absorption of fat-soluble vitamin K with hypoprothrombinemia

Surgical interference may be necessary at any time in the course of the disease either to save life, to render the patient a useful individual, or ultimately to provide a complete cure of the condition Ileostomy is the only proper initial procedure In fulminating cases, ileostomy is a life saving procedure is very disappointing and the risk may be greater than that of conservative treatment Except for the very acute violent manifestations of the disease ileostomy as a life-saving procedure usually implies that the physician has waited too long before calling for surgical help A proper attitude toward ileostomy is as follows when the patient ceases to be reasonably active because of his disease, ileostomy should be performed as an elective measure The newer mechanical devices at present available, skilful care of the operative site and the early employment of sealed collecting bags have appreciably reduced the handicaps of ileostomy life Total colectomy after ileostomy may be indicated and should be performed if diarrhea or bleeding persists or if acute exacerbations of the disease recur In disease of long standing either before or after ileostomy the danger of carcinomatous change in the colon should not be overlooked The incidence of cancer in chronic cases of this disease is undoubtedly higher than in the general population and the careful physician should constantly bear this in mind in planning adequate supervision of his patient An additional indication for ileostomy is the presence of intractable perianal sepsis recto vaginal fistulæ eye complications or crippling joint manifestations Acute perforation of the bowel obviously demands surgical intervention

# DISEASES OF THE LIVER

## GENERAL CONSIDERATIONS

An adequate understanding of hepatic disease must include a reasonable knowledge of liver anatomy and *function* Structurally the liver is composed of parenchymal (polygonal) cells, reticulo-endothelial cells (Kupffer cells), sinusoids biliary canaliculi and ducts stroma, and vascular elements Hepatic disease may involve primarily any of these anatomical structures Thus toxic or infectious agents may damage the parenchymal cells, thereby interfering with anabolic and catabolic processes essential to the body economy External interference with the ductal system may produce back pressure into the bile canaliculi, with resulting bile stasis and cholangitis Generalized disease of the reticuloendothelial system may involve these elements in the liver, or they may be affected directly by infectious agents or particulate matter Disease of the portal system or trauma to the hepatic artery or its radicles may reduce the blood supply of the liver to an important degree Congestive heart failure or pressure on the hepatic veins may prevent adequate venous return from the organ with resulting venous stasis, swelling and tissue anoxia In the early stages of any given disease any one of these elements may be solely affected As the disease process progresses, all the structural elements may become involved either in a diffuse necrotizing process or in the changes that accompany repair and scar tissue formation On the basis of our present knowledge, it is not possible to state that serious damage to the reticulo endothelial system is necessarily fatal Extensive damage to the parenchymal cells with destruction of a large number of these functional elements will invariably result in varying degrees of hepatic failure which may lead to coma and a fatal outcome Any consideration of the results of damage to the liver should include *a thorough realization of the fact that the* organ possesses tremendous powers of repair in the face of extensive damage Indeed it can be said that immediate survival after serious liver injury will depend upon the adequacy of the repair process in relation to the amount of parenchymal tissue destroyed regardless of architectural changes In the more chronic forms of liver disease compensation to structural damage will depend upon the degree of regeneration of functional elements The ultimate prognosis and the degree of useful activity that may be acquired in the presence of permanent liver damage will eventually depend upon the actual mass of functioning parenchymal cells Therapy therefore must be continuously directed toward those measures

Two other diagnostic measures should be mentioned first punch biopsy of the liver which has now been employed over a sufficient number of years to justify its occasional use both as a means of establishing a definite diagnosis and as a means of determining the probable stage or phase of the disease under consideration secondly radiological examination of the esophagus which is important in order to demonstrate the presence of esophageal varices as the cause of actual or potential bleeding in the presence of chronic liver disease

The *diagnosis* of liver disease in general will depend upon an adequate history, with full details as to exposure to infectious or toxic agents dietary habits and the duration and nature of individual symptoms Physical examination may yield little information but as a rule provides clear evidence of involvement of some part of the biliary system Icterus of the scleræ and skin enlargement of the liver and spleen the presence of a collateral circulation spider angiomata xanthomata and so-called liver palms give clear indication of hepatic disorder which may be primary or secondary to other serious disease Further evidence as to the severity of the underlying liver disease may be suggested by the finding of ascites and/or peripheral edema purpuric manifestations and the presence of a rather distinctive odor to the breath known as fetor hepatis In most instances a careful history and an equally careful physical examination will provide clear evidence that liver disease is present and frequently will indicate the essential nature of the process Information obtained by means of laboratory tests in most instances will be confirmatory of already established working diagnoses In other instances a definitive diagnosis will be impossible until the patient has been followed for an appreciable period of time or until surgical exploration has provided the final necessary information This last point is of extreme importance inasmuch as certain types of jaundice are extremely baffling and prolonged waiting for a final diagnosis may permit the occurrence of progressive hepatic failure to a point where proper surgical measures are ineffective because of the critical condition of the patient

*Treatment* —The general principles underlying the treatment of liver disease are clear In the presence of external biliary obstruction surgical relief of obstruction is essential and other measures will be of little or no value except in diminishing surgical risks In non-obstructive cases rest is important in order to reduce to a minimum the metabolic requirements of the individual At the same time, there must be adequate provision of nutrient material either orally or parenterally to spare the breakdown of body protein and to meet the tissue requirements necessary for the maintenance of metabolic processes and the repair of damage Thus a diet adequate in calories and relatively generous in protein is an essential therapeutic consideration Vitamin requirements may be met by properly balancing the diet or by the administration of specific substances as needed Noxious agents that may have been responsible for the liver damage must be eliminated and drugs or other specific substances that might further harm the liver must be avoided Specific infection must be controlled either by adequate surgical drainage of the biliary tract if an obstructive process is present or by the use of suitable antibiotics Transfusions will serve to replace blood that has been lost through hemorrhage or temporarily raise hemoglobin levels where hematopoiesis is diminished In rare instances low serum albumin levels may be temporarily raised with benefit to the patient by the intravenous use of human serum albumin Because of the frequent occurrence of pain and restlessness analgesics or sedatives may be needed Morphine and opium derivatives should be used with extreme caution in the presence of a sick liver inasmuch as they are conjugated slowly and rather inadequately with the result that an ordinary dose may become an overdose The same caution should be observed in the use of the barbiturates Control of fluid and electrolyte balances will be treated in the discussion of specific manifestations of liver disease Ascites and peripheral edema may require the use of a low sodium diet mercurial diuretics and under proper circumstances the employment of ion-exchange resins

Brief consideration should be given to the differentiation of various types of hyperbilirubinemia. In hemolytic jaundice of any type in which there is an excessive amount of bilirubin in the serum resulting from abnormal breakdown of red blood cells, there is an absence of prompt direct reacting bile pigment and of bilirubinuria (acholuric jaundice). Such a finding in the serum is also to be noted in the jaundice encountered in instances of icterus neonatorum and in so-called constitutional hepatic dysfunction, in which only an indirect van den Bergh reaction is found. In disease conditions affecting primarily the integrity of the liver parenchyma or in frank biliary obstruction total serum bilirubin will consist of two components measured by the van den Bergh test (1) prompt, direct reacting serum bilirubin (one-minute bilirubin) and (2) total bilirubin (indirect-reacting bilirubin). The relationship between the prompt-reacting fraction and total bilirubin has little definitive diagnostic importance, although high values for the prompt reacting fraction are most frequently found in cases of uncomplicated extrahepatic obstruction.

Tests of metabolic functions of the liver are numerous and varied. In the absence of jaundice, the most delicate test of impaired parenchymal-cell function is that obtained by the administration of bromsulphalein by vein (5 mgm. per kilogram of estimated body weight) and the determination of the amount of dye retained in the blood serum at the end of 45 minutes. Acute severe liver damage usually results in an alteration of the albumin globulin fractions of the blood plasma. The cephalin-cholesterol flocculation and thymol turbidity and flocculation are positive and the gamma globulin concentration in the serum is high. In the very acute, severe manifestations of hepatic disorders or in the more chronic forms there is a tendency to a steady diminution in the level of serum albumin and an associated rise in the globulin values particularly that of gamma globulin. The total serum protein may fall below normal levels but, more frequently, is essentially normal with an inversion of the albumin globulin ratio. Determination of this ratio *per se* yields little prognostic or therapeutic information but the actual level of serum albumin gives significant information of the functional capacity of the liver in the absence of recent bleeding. The demonstration of hypoprothrombinemia may indicate merely interference with proper excretion of bile into the intestinal tract. A diminished plasma prothrombin may also provide a very adequate indication of parenchymal-cell damage, and this will be readily confirmed by failure to rectify this abnormality following the administration parenterally of vitamin K. Less satisfactory tests of impairment of certain metabolic functions of the liver are to be obtained by the use of the galactose-tolerance test and hippuric acid test, and the determination of the ratio between cholesterol esters and total serum cholesterol. Measurement of urobilinogen in the urine in the absence of any degree of external biliary-tract obstruction, provides a relatively simple means of estimating parenchymal cell damage. Increased urinary values nearly always signify rather extensive damage and a return toward normal levels in the absence of increasing obstruction provides a favorable prognostic sign.

The selection of any of these tests, in most instances should be based upon a careful clinical evaluation of the individual case. At times the whole "battery" of tests is necessary in order to obtain adequate diagnostic help. In most instances however a working diagnosis will enable the physician to choose a small number of tests to be employed in order to gain confirmatory evidence as to the nature of the underlying condition without undue loss of time or unnecessary expense to the patient. It should be remembered that no single test is diagnostic and that even in classical cases of certain forms of liver disease certain tests may be temporarily quite misleading. Thus in parenchymal disease of the liver one or more of the flocculation tests occasionally may be entirely negative. Similarly in minor degrees of jaundice bromsulphalein retention may unexpectedly fall within normal limits. In any given case it is important to choose those tests the results of which are positive and then follow these consistently in order to determine the progress and trends of the disease process.

disease Pertinent laboratory procedures will include examination of the urine and the stools As a rule, the stools will show a moderate or normal amount of bile pigment on gross examination The urine will contain not only bilirubin but excessive amounts of urobilinogen The results of flocculation tests may be definitely positive and the cholesterol esters will usually be found to be definitely diminished In severe cases leukocytosis will be present indicating a severe degree of necrosis

*Treatment* obviously must include removal of the noxious agent particularly if this is a recently administered drug Absolute rest is necessary and an adequate amount of fluid and a well balanced diet are essential In the milder cases these two measures can be provided without difficulty In cases in which anorexia nausea and vomiting exist feeding may be difficult and parenteral therapy may be necessary In moderately severe cases small amounts of simple food may be tolerated and the remainder may be supplied by vein in the form of dextrose solutions in saline or in water depending upon the amount of vomiting that has taken place At times the use of constant feeding through a nasal catheter may make it possible to meet dietary requirements in cases in which nausea interferes with proper oral feeding Under such circumstances the use of milk powder Karo or banana powder and moderate amounts of Brewers yeast may provide a satisfactory mixture Where severe liver damage has occurred it may be wise to use concentrated solutions of dextrose (25 per cent solution) in order to meet caloric requirements spare the breakdown of body protein and obviate the administration of excessive quantities of fluid The use of lipotropic substances such as methionine or choline probably offers little if adequate nutrient material can be given by mouth Where this is impossible one of these agents may be given parenterally in the hope that it may prove of some benefit The use of vitamin B concentrates is usually advocated but there is little evidence that they contribute much to effective therapy If the patient tolerates a good diet they are not needed If ingestion of food is limited vitamin preparations may be given by vein but it should be remembered that niacin amide may not be utilized by a sick liver and may compete for methyl groups which might otherwise be utilized in the natural formation of choline from methionine-containing substances If sedation is necessary because of restlessness muscular tremor or convulsions it is wise to avoid the use of the barbiturates and to employ safer preparations such as chloral hydrate or paraldehyde Morphine or opium derivatives or synthetic substances such as demerol or methedon should be used with great caution if necessary to control abdominal pain Where it is obvious that the liver is severely damaged these preparations are probably contraindicated

*Prognosis* —As noted above the prognosis in toxic damage to the liver will depend upon the dosage of the specific poison the length of the exposure and the susceptibility of the patient If there is coexisting malnutrition chronic alcoholism diarrhea or any other debilitating condition the outlook may be extremely grave and the need for replacement therapy immediate Once the diagnosis of intrahepatic damage is made regardless of the underlying cause continuous intensive treatment is necessary until the patient shows striking signs of improvement The term *acute yellow atrophy* already alluded to does not represent a specific disease entity It merely is an indication of a severe necrotizing destructive process that may occur in the presence of any form of liver injury that is extensive and progressive The greater the degree of atrophy the greater the degree of liver insufficiency and the worse the prognosis

VIRAL HEPATITIS (ACUTE CATARRHAL JAUNDICE EPIDEMIC INFECTIOUS JAUNDICE SERUM HEPATITIS) —Under this heading should be included what for many years was classified as acute catarrhal jaundice For therapeutic purposes epidemic infectious hepatitis and serum hepatitis can be grouped together as representing serious diffuse infection of the liver probably by specific viruses Clinically the two conditions should be differentiated because of differences in the manner in which the disease is acquired in the incubation period and in immune responses Either of these two

## SPECIFIC DISEASES OF THE LIVER

*The diseases of the liver may be roughly* classified into acute and chronic They may be further divided into conditions due to specific agents toxic to the liver or specific infections of the liver conditions associated with degenerative changes, disorders due to obstruction either in the external biliary ducts or in the bile canaliculi and finally infiltrating neoplasms

TOXIC HEPATITIS —Acute damage to the liver may result from a variety of known agents Among these are certain chemicals such as chloroform, carbon tetrachloride trichlorethylene, tetrachlorethane, trinitro toluol, phosphorus tannic acid, beryllium arsenic cincophen and many other sub stances All these agents cause diffuse hepatic damage with necrosis of parenchymal cells In most instances the toxic agents produce rather acute hepatic damage with rapidly progressing symptoms of liver insufficiency In the case of beryllium and certain inorganic arsenic compounds the process may develop much more slowly The lesions produced in the liver by these various agents vary considerably Thus beryllium poisoning produces diffuse gran ulomatous change in the organ and is rarely associated with acute hepatic insufficiency Arsphenamine and cincophen for example involve the entire hepatic lobule Central necrosis is caused by chloroform carbon tetrachloride, and the like The lesions due to phosphorus primarily *involve the periphery* of the lobule In spite of histological differences liver damage due to noxious agents such as those noted above is a diffuse process, which involves the entire organ and is accompanied by varying degrees of parenchymal-cell destruction and loss of primary hepatic functions The degree of damage will depend upon the dose of the poisonous substance the duration of exposure and the susceptibility of the individual patient In any event, the clinical manifestations of this type of insult to the liver produce hepatic insufficiency, which in extreme cases may progress to a fatal outcome because of the destruction of a sufficient number of paren chymal cells In most instances, jaundice is the presenting clinical feature Loss of appetite nausea, and vomiting are com monly encountered and may steadily in crease in severity Where only mild intoxi cation is present, physical signs in addition to icterus may reveal moderate hepatic enlargement, with local tenderness In the more severe cases jaundice will be more intense and hepatic enlargement and tender ness will at first be more striking If a great deal of damage has been produced, necrosis of the liver may progress in spite of attempts at repair, until real hepatic failure is present At this point, the picture of acute yellow atrophy may be present with a gradual diminution in size of the liver and the devel opment of abdominal distention, which is in the nature of a paralytic ileus Ascites may occur The patient will become restless muscular movements may become jerky or convulsive and finally, drowsiness and coma may supervene A heavy mousy odor may be noted on the breath at any stage of the condition and is usually evidence of pro found liver damage A point of clinical importance is that patients with diffuse damage to the liver parenchyma, on the basis either of toxic agents or of infection may apparently be progressing favorably and then almost without warning deteriorate rapidly and slip into a terminal coma Among important prognostic features should be noted increasing oliguria and a steady rise in pulse rate and in temperature A progres sively diminishing urinary output is always a bad prognostic sign Conversely, a stead *ily increasing urinary output except as a* rare terminal event indicates a favorable response to therapy

*Diagnosis* —The diagnosis will usually be apparent from the physical signs noted above together with a history which will indicate exposure to a toxic agent and a story of recent and rapidly developing symptoms At times initial diagnosis may be difficult because of the fact that the patient may complain of right upper-quadrant pain which with the local tenderness and jaun dice may suggest the possibility of a stone in the common duct or acute cholecystitis The degree of prostration and the diffuse tenderness to palpation or compression of the liver will be points in favor of intrahepatic

persists until the disease abates Itching is a variable feature, which may be so extreme as to produce intense scratching with excoriation of the skin and sometimes, superficial skin infection In fulminating cases or cases in which there is extreme progressive derangement of liver function striking atrophy of the liver may occur, with demonstrable reduction in size and the concomitant signs of hepatic failure previously described

*Diagnostic Measures* —The diagnosis is usually easily made on the basis of history and physical findings In most instances laboratory studies reveal varying grades of hyperbilirubinemia and the presence of bilirubin in abnormal amounts in the urine, and in diminished quantities in the stools Urinary urobilinogen at first is increased but subsequently may fall to normal or subnormal levels again rising however, during the recovery period to high levels before eventually returning to normal In the most severe cases albuminuria is a constant finding together with the appearance of cellular elements and casts Before intense jaundice has appeared, the bromsulphalein test may be one of the first to show striking abnormalities Subsequently flocculation tests will become positive and will usually remain so during the active course of the disease Alkaline phosphatase and cholesterol levels may be moderately elevated, and on occasion alkaline phosphatase values in the serum may reach very high levels due to intracanalicular block Prothrombin values are usually reduced depending upon the severity of the disease The level of cholesterol esters is nearly always lowered In the pre icteric stage of the disease a transient leukocytosis may occur Subsequently however the white blood count is usually below normal and may reach very low levels with an absolute reduction in the number of circulating granulocytes Monocytic cells will be relatively or actually increased typically they assume rather bizarre forms forms at times difficult to differentiate from those encountered in infectious mononucleosis These blood changes have been fully described by Jones and Minot In cases of moderate or greater severity erythrocyte levels will drop and the red-cell count may go as low as 2 million red blood cells per cubic millimeter The sedimentation rate at first is normal but gradually becomes accelerated and may be the last laboratory finding to remain positive as evidence of active disease If diagnosis is extremely difficult aspiration biopsy of the liver invariably shows a characteristic histological picture

Radiological studies are chiefly of value in excluding other causes of jaundice although they may occasionally provide diagnostic help by demonstrating an otherwise unsuspected splenic enlargement In certain rare instances examination by barium meal may reveal distortions of the mucosal pattern of the duodenum which are distinguished with difficulty from those due to cancer of the head of the pancreas or the ampulla These changes may be due to frank duodenitis or to pressure on the duodenum by enlarged periductal glands When noted, they should always suggest the possibility of a malignant process, but the presence of laboratory findings entirely consistent with intrahepatic disease rather than typical of external block may make it reasonable to disregard such a possibility

*Course* —In the average case the course of the disease covers a period of from two to four weeks In severe cases it may last for weeks or months and cause marked loss of weight and strength Convalescence is slow, and recovery of strength very gradual The prolongation of the disease over eight or ten weeks indicates a possible change from an acute condition to a continuing, progressive, subacute process Subacute hepatitis eventually leading to so-called post atrophic cirrhosis is fortunately uncommon In fulminating cases, death may occur in from three to five days The disease may apparently progress favorably for several weeks and then suddenly show evidences of greater degrees of liver destruction with an abrupt fatal termination The mortality rate for infectious hepatitis of the epidemic variety is probably no greater than 2 or 3 per cent

*Treatment* —The general principles of rest and the provision of an adequate amount of nutrient material constitute the chief therapeutic measures In the acute stage of the disease it is important that the patient be kept at full rest In the recovery period,

conditions may occur at practically any age They may be encountered sporadically or, in the case of epidemic infectious hepatitis, in true epidemics Serum hepatitis may occur in large groups of individuals and this was the case during World War II, when a specific infectious agent was transmitted by inoculation to large groups of individuals The etiological agent responsible for either type of hepatitis has not yet been fully identified but the work of Stokes, Havens, Neefe, and others presents very convincing evidence of a viral origin for these maladies Stokes and his collaborators have recently cultivated an ultra-filterable agent which may prove to be the cause of the epidemic form of the infection, and skin tests based on this finding are probably of diagnostic significance

### *Epidemic Infectious Hepatitis*

This condition is due to an agent that can be transmitted to human beings by material obtained from stools of patients with the disease Therefore it is presumably transmitted by flies and other insects and by human carriers who pollute food and other ingesta Fecal contamination of water has been shown to be a source of epidemics Inhalation of infectious material probably does not cause the disease, except in rare instances It is also doubtful whether the disease is transmitted by means of inoculation with infected instruments or solutions The average incubation period of the disease is approximately three weeks but may vary from two to six weeks

The *histological changes* taking place in the liver in this disease consist characteristically of necrosis of the parenchymal cells of greater or less degree sometimes involving individual cells, sometimes involving wide areas of hepatic tissue Cellular infiltration occurs in these areas Ordinary regeneration of parenchymal damage is complete and leaves little or no evidence of the disease but, in the fulminating cases, evidences of regeneration are minimal, and almost complete autolysis of the liver may occur In subacute cases regeneration occurs in an irregular fashion, with complete change in the liver architecture, due to fibrosis and *condensation of hepatic units* Eventually, the process may go on to the full blown picture of cirrhosis

The onset of *symptoms* is characteristically abrupt and may be ushered in by chills and fever Nausea and vomiting with marked loss of appetite and a distaste for food are quite characteristic, diarrhea may occur In some instances symptoms occur so gradually as to be unnoticed for days, but in almost every instance there is eventually a lack of desire for food and nausea if not frank vomiting Abdominal pain may occur as an early symptom and may be sufficiently severe to suggest the possibility of cholelithiasis or cholecystitis, particularly if jaundice is present Usually, within from ten days to two weeks of the initial symptoms, scleral icterus and the appearance of dark urine and light-colored stools are noted The disease may occur however, without ever showing clinical icterus or even hyperbilirubinemia a fact of clinical significance inasmuch as the correct diagnosis may be missed completely and inadequate therapy may be instituted In the vast majority of cases, fever is not present once clinical icterus is noted a point of importance in differentiating virus hepatitis from conditions such as cholelithiasis, cholangitis, pylephlebitis multiple liver abscesses *etc*

On *physical examination* the most important sign is that of a slightly enlarged liver, which is tender to palpation or compression Icterus is usually present and may become intense in the course of a few days or may remain at a very minimal level Slight enlargement of the spleen should be looked for as confirmatory evidence of liver disease, and with care can be demonstrated by palpation or percussion in possibly half of the cases Demonstration of splenic enlargement is of particular importance in differentiating cases of infectious hepatitis from jaundice secondary to occlusion of the common duct in which splenomegaly is not to be expected Generalized lymphadenopathy may occasionally be encountered In severe cases abdominal distention ascites and peripheral edema may occur and occasionally spider angiomata are observed One characteristic phenomenon is the frequent association with mental depression which

cent have been reported Diagnostic and therapeutic measures differ in no way from those discussed in the preceding section One point of clinical importance lies in the fact that so-called serum hepatitis particularly that occurring sporadically frequently follows perfectly proper surgical procedures The appearance of jaundice a few months after upper abdominal surgery may erroneously be considered a complication of the surgical procedure and result in an exploratory laparotomy Such a decision is extremely unfortunate and may result in a fatal outcome if the jaundice is due to intrahepatic infection Therefore it is of extreme importance in postoperative patients to determine the period of time elapsing between the operation and the appearance of icterus inasmuch as this may give the first clue as to the underlying condition Confirmatory and suggestive evidence may further be found in the fact that the patient has received a number of whole-blood transfusions or still more important one or more units of plasma When these facts can be elicited it is essential that all the findings be carefully evaluated with the aid of appropriate liver function tests in order to avoid unnecessary and dangerous surgery

*Prevention* —Whenever possible all instruments that might carry the infectious agent such as solid and hollow needles scalpels *etc* should be carefully autoclaved before use and not used again until further similar sterilization has been provided Transfusions with whole blood should not be provided from donors who have had jaundice within the preceding three months The use of plasma should be limited to emergencies and as far as possible plasma units should be derived from the smallest possible pools Human fibrin preparations should be used with great caution and should indeed be avoided unless products of animal origin are unobtainable Partial sterilization of plasma may be obtained through ultraviolet irradiation and possibly through the use of nitrogen mustard Neither of these measures however affords full protection against contamination As in the epidemic form one attack of the disease almost always protects against further infection The use of gamma globulin probably has no value as a prophylactic measure

Other Acute Hepatic Infections — Among other infections primarily affecting the liver mention should be made of such conditions as yellow fever spirochetosis ictero-hemorrhagica infectious mononucleosis typhoid and parasitic infestations such as amebiasis and schistosomiasis These disease entities are fully covered in other sections However brief mention should be made of *infectious mononucleosis* This condition occasionally closely simulates infectious hepatitis Differential points in the diagnosis are the more generalized adenopathy and the greater enlargement of the spleen that are usually encountered in infectious mononucleosis as well as the positive heterophile agglutination usually present after the initial stages of the disease and the characteristic changes in circulating leukocytes In infectious mononucleosis leukocytosis is common and leukopenia rare In most of the cases the appearance of monocytes is diagnostic

*Acute biliary obstruction* is practically always the result of interference with the normal flow of bile through the external biliary passages into the duodenum by biliary calculi new growth postoperative trauma to the common duct or the pressure on the common duct of enlarged glands due to infectious disease It may also occur as the result of a congenital anomaly atresia of the common bile duct Unless accompanied by serious infection of the biliary radicles proximal to the level of obstruction little actual damage to the liver results When obstruction persists for any period of time back pressure occurs with dilatation of the biliary radicles and infection by coliform or or other enteric organisms When uncorrected there may be eventual deterioration of hepatocellular function with resulting hepatic insufficiency The condition is essentially a surgical one and adequate drainage measures are always indicated with appropriate added measures to control any infection that is present Postponement of surgical intervention except where obstruction is due solely to the enlargement of lymph glands in the course of infectious disease or is a manifestation of metastatic

moderate exercise should be permitted but should always be kept below fatigue levels. The use of alcohol during or immediately after attacks of hepatitis should be prohibited, as should the use of medications that are known to be hepatotoxic agents. The point at which full activity should be allowed is not always easy to determine, but in general it can be stated that too early ambulation with associated physical fatigue may produce relapses, with at times sudden painful enlargement of the liver and an increase in jaundice. The persistence of a rapid sedimentation rate, positive results in flocculation tests, abnormal bromsulphalein retention, or definite hypoprothrombinemia should warrant continued conservative treatment. A slightly elevated serum bilirubin *does not necessarily indicate* continued activity of the process. In fulminating or very severe cases therapy must be pushed continuously in the hope of saving life or of protecting the liver from irreparable damage. In cases in which a subacute or chronic process evolves, a carefully planned program of therapeutic measures and of regulated activity must be outlined. The use of antibiotics in the acute stages of the disease has proved to be of no value whatever. At the present time limited studies suggest that the course of the disease may be shortened appreciably by the use of corticosteroids but, to date, the evidence is not conclusive and ultimate decision as to this form of therapy must wait for further careful clinical investigation.

*Prophylactic measures* are of importance in order to prevent the spread of the epidemic form of the disease. Personnel caring for individuals ill with epidemic infectious hepatitis should be extremely careful to wash their hands carefully after handling the patient. Bed linen and fomites should be treated with infectious precautions. In institutions or in groups of individuals among whom the disease appears an important degree of protection for exposed persons may be obtained by the use of gamma globulin which contains immune bodies.

*Immunity*.—In most instances a single attack of the disease confers a lasting immunity, but recurrences after long intervals have been reported. It is extremely important to note that this disease does not confer immunity to infection by the agent responsible for serum hepatitis, and the converse is equally true.

### Serum Hepatitis

Serum hepatitis is quite similar to the entity described above in that it represents an acute diffuse infectious process involving the liver parenchyma, with varying degrees of liver damage and insufficiency. Certain important characteristics should be noted. This disease is acquired in almost every *instance by the introduction of the* infectious agent through the skin. Transmission by ingestion or inhalation probably does not occur, or only on rare occasions. The agent may be introduced by venipuncture needles contaminated from other individuals harboring the disease and by the use of infected whole blood, plasma, or other blood products such as human fibrin. It may be transmitted as a laboratory accident from contaminated instruments or containers. After inoculation of infected material in the course of group immunization to specific disease the most common source of infection is in the therapeutic use of whole blood or its fractions. The use of plasma is more dangerous than that of whole blood inasmuch as plasma is usually derived from a fairly large pool of donors, any one of whom may contribute the infectious agent. Commercially prepared fibrin for use in surgical operations constitutes another serious source of the disease if the fibrin product is of human origin. As far as the danger arising from contaminated instruments and containers is concerned, full protection can be obtained only by sterilization under autoclave conditions.

The incubation period of the disease, unlike that of epidemic infectious hepatitis, averages about three months; it may vary from two to possibly six months. The onset and the subsequent course of the disease are essentially the same as the onset and the course of the epidemic form of hepatitis but available statistical evidence would indicate that the condition carries a higher mortality rate than the epidemic form. Mortality rates as high as from 10 to 14 per

cent have been reported. Diagnostic and therapeutic measures differ in no way from those discussed in the preceding section. One point of clinical importance lies in the fact that so-called serum hepatitis, particularly that occurring sporadically, frequently follows perfectly proper surgical procedures. The appearance of jaundice a few months after upper abdominal surgery may erroneously be considered a complication of the surgical procedure and result in an exploratory laparotomy. Such a decision is extremely unfortunate and may result in a fatal outcome if the jaundice is due to intrahepatic infection. Therefore it is of extreme importance in postoperative patients to determine the period of time elapsing between the operation and the appearance of icterus, inasmuch as this may give the first clue as to the underlying condition. Confirmatory and suggestive evidence may further be found in the fact that the patient has received a number of whole blood transfusions or, still more important, one or more units of plasma. When these facts can be elicited it is essential that all the findings be carefully evaluated with the aid of appropriate liver function tests in order to avoid unnecessary and dangerous surgery.

*Prevention.*—Whenever possible all instruments that might carry the infectious agent, such as solid and hollow needles, scalpels, *etc.*, should be carefully autoclaved before use and not used again until further similar sterilization has been provided. Transfusions with whole blood should not be provided from donors who have had jaundice within the preceding three months. The use of plasma should be limited to emergencies and, as far as possible, plasma units should be derived from the smallest possible pools. Human fibrin preparations should be used with great caution and should indeed be avoided unless products of animal origin are unobtainable. Partial sterilization of plasma may be obtained through ultraviolet irradiation and possibly through the use of nitrogen mustard. Neither of these measures, however, affords full protection against contamination. As in the epidemic form, one attack of the disease almost always protects against further infection. The use of gamma globulin probably has no value as a prophylactic measure.

Other Acute Hepatic Infections.—Among other infections primarily affecting the liver, mention should be made of such conditions as yellow fever, spirochetosis ictero-hemorrhagica, infectious mononucleosis, typhoid, and parasitic infestations such as amebiasis and schistosomiasis. These disease entities are fully covered in other sections. However, brief mention should be made of *infectious mononucleosis*. This condition occasionally closely simulates infectious hepatitis. Differential points in the diagnosis are the more generalized adenopathy and the greater enlargement of the spleen that are usually encountered in infectious mononucleosis, as well as the positive heterophile agglutination usually present after the initial stages of the disease and the characteristic changes in circulating leukocytes. In infectious mononucleosis leukocytosis is common and leukopenia rare. In most of the cases the appearance of monocytes is diagnostic.

*Acute biliary obstruction* is practically always the result of interference with the normal flow of bile through the external biliary passages into the duodenum by biliary calculi, new growth, postoperative trauma to the common duct, or the pressure on the common duct of enlarged glands due to infectious disease. It may also occur as the result of a congenital anomaly, atresia of the common bile duct. Unless accompanied by serious infection of the biliary radicles proximal to the level of obstruction, little actual damage to the liver results. When obstruction persists for any period of time back pressure occurs with dilatation of the biliary radicles and infection by coliform or or other enteric organisms. When uncorrected there may be eventual deterioration of hepatocellular function with resulting hepatic insufficiency. The condition is essentially a surgical one and adequate drainage measures are always indicated with appropriate added measures to control any infection that is present. Postponement of surgical intervention, except where obstruction is due solely to the enlargement of lymph glands in the course of infectious disease, or is a manifestation of metastatic

malignancy or a generalized process such as Hodgkin's disease, will invariably result in irreparable liver damage and may prove fatal. Brief mention should be made of obstructive jaundice secondary to congenital atresia of the bile duct or ampulla. Although uncommon, this condition should be immediately diagnosed in infants presenting feeding difficulties almost immediately after birth, difficulties associated with the gradual but steady appearance of icterus. The only condition to be considered in differential diagnosis is that of icterus neonatorum which can be readily diagnosed by appropriate blood studies and the demonstration of an acholuric jaundice. Immediate surgical intervention is necessary to correct the condition of atresia. In any severe obstructive episode, a necessary *preparation for successful surgery is the adequate use of vitamin K and the availability of fresh whole blood for transfusion during the operative procedure.

CHRONIC DISEASE OF THE LIVER (CHRONIC HEPATITIS, CIRRHOSIS).—Chronic liver disease may be the result of previous damage by toxic agents, specific infections, progressive degenerative disease, prolonged partial obstruction to the flow of bile, and various types of vascular disturbances. The disease process may continue for months following an acute episode of liver damage, in which case it is usually classified as chronic hepatitis. Repeated insults or a continuation of the original process may result in a slowly progressive alteration in the entire structure of the liver, with the constant balancing of destructive and reparative processes and resulting fibrosis. This may be properly considered a chronic hepatitis as has been suggested by Bloomfield, although it is more commonly classified under the heading of cirrhosis. Inasmuch as the term *cirrhosis* implies only a chronic fibrosing change in the liver, the term has lost its original significance of a disease entity. It should serve merely as a descriptive term for late and far advanced hepatic disorders, characterized by profound structural changes in the organ and ultimately, marked deforming sclerosis. Whatever the underlying cause, chronic hepatitis or cirrhosis represents the composite result of destruction and repair. The actual replacement of degenerated or destroyed parenchymal tissue may be adequate in amount, in which event hepatic function may be competent and the condition may be described as compensated. Replacement of liver damage by scar tissue and, in fact, excessive regeneration of parenchymal cells may interfere with the intrinsic blood supply of the various functioning units of the liver and eventually result in greater or lesser degrees of hepatic incompetence. Furthermore, scar-tissue *formation may* compress the portal radicles in the liver, with resulting portal hypertension and the formation of varicosities, particularly in the esophagus *and the upper gastrointestinal tract but also* in the inferior hemorrhoidal veins. The varicosities provide a source of future danger from hemorrhage. In the final analysis the duration of survival in the presence of chronic liver disease will depend upon the existence of a sufficient number of functioning units, old or new. It is essentially a quantitative problem. If the repair process is quantitatively adequate, compensation results provided the demands of the individual patient do not exceed the ability of the liver to meet metabolic requirements. If regeneration has not been quantitatively adequate, then symptoms of hepatic insufficiency appear with measurable loss of specific liver function.

In general, the outstanding symptom of chronic liver disease is that of easy fatigability due to a failure to meet general metabolic requirements. In addition, specific symptoms and signs appear in decompensated cirrhosis as the result of very special hepatic activities. Thus a normocytic anemia with a lowering of the red-cell count and the hemoglobin, is commonly encountered. At times the anemia may be macrocytic due to lack of ability to provide the factor necessary to mature erythrocytes. Hypoprothrombinemia may be present with resulting spontaneous hemorrhages and purpura, and failure to conjugate estrogens may result in gynecomastia, testicular atrophy and loss of axillary hair. Jaundice may be present due solely to a widespread interruption of normal canalicular continuity. Vascular *changes may occur resulting* in the formation of spider angiomata and the appearance of so-called liver palms. Peripheral edema

ascites and hydrothorax may appear because of a reduction in plasma osmotic pressure secondary to a lowering of serum albumin An added factor in the production of ascites is undoubtedly the existence of portal hypertension Neither the factor of a lowered plasma osmotic pressure nor that of portal hypertension alone can be held responsible for this phenomenon Regardless of the type of disease underlying the chronic hepatic disturbance episodes of fever are not uncommon They can be most reasonably explained on the hypothesis that the liver is unable by its normal bacteriolytic processes satisfactorily to handle organisms coming to it from the digestive tract Episodes of pain that are entirely comparable to attacks of biliary colic are occasionally encountered These may at times be due to a sudden stretching of the liver capsule but more frequently than not no satisfactory explanation can be adduced other than the fact that chronic liver disease exists Weakness on exertion may be extreme and at times episodes simulating attacks of hypoglycemia occur episodes which may even result in temporary unconsciousness Itching may be present in any form of chronic liver disease either with or without jaundice although as a rule it is associated with evidences of external obstruction to the flow of bile

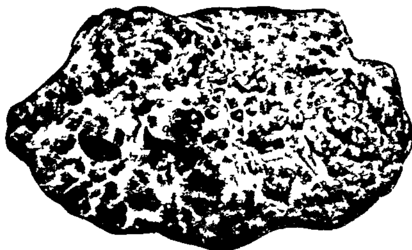
The physical signs of chronic liver disease are essentially those which have already been discussed They will vary tremendously according to the stage of the disease that exists at the time of examination Alterations discovered through laboratory tests undergo similar variations Generally in compensated liver disease the most common findings are moderate anemia slight bromsulphalein retention positive results in the flocculation tests and a tendency to a lowering of the serum albumin Hyperbilirubinemia is not a feature unless chronic partial obstruction exists When the intrahepatic process undergoes an exacerbation of its activity all functional tests become more abnormal and if there is active degeneration of parenchymal tissue hyperbilirubinemia increases usually in association with tenderness and enlargement of the liver Intercurrent infection hemorrhage operative procedures and the use of drugs that may be toxic to the liver commonly result in exacerbations of the underlying disease with an increase in symptoms and marked alterations of all functional tests For example an attack of pneumonia in a patient with compensated cirrhosis or an unavoidable surgical operation may be immediately followed by the appearance of jaundice liver enlargement ascites and peripheral edema Major hemorrhage from esophageal varices or from any other source may be associated with similar abrupt changes and the tendency to ascites and edema may be intensified by the loss of plasma albumin and the replacement of fluid by physiological saline It is to be noted that following severe hemorrhage in patients with cirrhosis and splenic enlargement there may be a temporary but striking reduction in the size of the spleen One point of extreme importance is that the appearance of edema, and particularly of ascites, is not necessarily an irreversible phenomenon Ascites may appear merely as an acute transient phenomenon that is entirely reversible It may not recur for months or years and then only as a result of further serious liver damage In the presence of chronic liver disease the disappearance of ascites under proper medical management provides in itself a very hopeful prognostic fact

Chronic hepatitis or cirrhosis may be classified for practical purposes under six headings (1) post atrophic cirrhosis (2) Laennec's or portal cirrhosis (3) biliary cirrhosis (4) syphilitic cirrhosis (5) cardiac cirrhosis and (6) parasitic cirrhosis

### Post-atrophic Cirrhosis

Post atrophic cirrhosis as the name implies is the late result of progressive continuing chronic hepatitis presumably viral in origin Undoubtedly cases also occur as the result of the action of specific poisons in initiating degenerative changes From the case history one may be able to obtain a continuous story of liver disease covering months or years starting with a typical attack of infectious hepatitis In many instances such a history is lacking and the

malignancy or a generalized process, such as Hodgkin's disease, will invariably result in irreparable liver damage and may prove fatal. Brief mention should be made of obstructive jaundice secondary to congenital atresia of the bile duct of ampulla. *Although* uncommon, this condition should be immediately diagnosed in infants presenting feeding difficulties almost immediately after birth, difficulties associated with the gradual but steady appearance of icterus. The only condition to be considered in differential diagnosis is that of icterus neonatorum, which can be readily diagnosed by appropriate blood studies and the demonstration of an acholuric jaundice. Immediate surgical intervention is necessary to correct the condition of atresia. In any severe obstructive episode, a necessary preparation for successful surgery is the adequate use of vitamin K and the availability of fresh whole blood for transfusion during the operative procedure.



CHRONIC DISEASE OF THE LIVER (CHRONIC HEPATITIS, CIRRHOSIS).—Chronic liver disease may be the result of previous damage by toxic agents, specific infections, progressive, degenerative disease, prolonged partial obstruction to the flow of bile, and various *types of vascular disturbances*. *The disease* process may continue for months following an acute episode of liver damage, in which case it is usually classified as chronic hepatitis. Repeated insults or a continuation of the original process may result in a slowly progressive alteration in the entire structure of the liver, with the constant balancing of destructive and reparative processes and resulting fibrosis. This may be properly considered a chronic hepatitis, as has been suggested by Bloomfield, although it is more commonly classified under the heading of cirrhosis. Inasmuch as the term *cirrhosis* implies only a chronic, fibrosing change in the liver, the term has lost its original significance of a disease entity. It should serve merely as a descriptive term for late and far-advanced hepatic disorders characterized by profound structural changes in the organ and, ultimately, marked deforming sclerosis. Whatever the underlying cause, chronic hepatitis or cirrhosis represents the composite result of destruction and repair. The actual replacement of degenerated or destroyed parenchymal tissue may be adequate in amount, in which event hepatic function may be competent and the condition may be described as compensated. Replacement of liver damage by scar tissue and, in fact, *excessive regeneration of parenchymal cells* may interfere with the intrinsic blood supply of the various functioning units of the liver and eventually result in greater or lesser degrees of hepatic incompetence. Furthermore, scar tissue formation may compress the portal radicles in the liver, with resulting portal hypertension and the formation of varicosities, particularly in the esophagus and the upper gastrointestinal tract but also in the inferior hemorrhoidal veins. The varicosities provide a source of future danger from hemorrhage. In the final analysis, the duration of survival in the presence of chronic liver disease will depend upon the existence of a sufficient number of functioning units, old or new. It is essentially a quantitative problem. If the repair process is quantitatively adequate, compensation results, provided the demands of the individual patient do not exceed the ability of the liver to meet metabolic requirements. If regeneration has not been quantitatively *adequate, then symptoms of hepatic insufficiency* appear, with measurable loss of specific liver function.

In general, the outstanding symptom of chronic liver disease is that of easy fatigability due to a failure to meet general metabolic requirements. In addition, specific symptoms and signs appear in "decompensated cirrhosis" as the result of very *special hepatic activities*. Thus, a normocytic anemia with a lowering of the red-cell count and the hemoglobin is commonly encountered. At times, the anemia may be macrocytic due to lack of ability to provide the factor necessary to mature erythrocytes. Hypoprothrombinemia may be present, with resulting spontaneous hemorrhages and *purpura*, and failure to conjugate estrogens may result in gynecomastia, testicular atrophy, and loss of axillary hair. Jaundice may be present due solely to a widespread interruption of normal canalicular continuity. Vascular changes may occur, resulting in the formation of spider angiomata and the appearance of so-called *liver palms*. *Peripheral edema*

presumption is that the original insult occurred during an acute attack of an unrecognized, non icteric infectious hepatitis. The history may reveal exposure to known toxic substances, such as carbon tetrachloride, chloroform, cincophen, and the like. Typically, there is moderate enlargement of the liver and spleen, but, as the disease continues, the liver becomes progressively smaller until it can be demonstrated only with difficulty on physical examination. Unless the diagnosis is suggested by history or by histological study of tissue obtained by aspiration biopsy, the condition is clinically indistinguishable from Laennec's cirrhosis. Grossly and microscopically, the liver architecture is tremendously altered with evidence of widespread liver necrosis and regeneration. Irregular lobules of regenerated liver cells will be noted with condensation of bile ducts and liver reticulum and with large bands of connective tissue. The entire picture is that of a disorderly arrangement of liver structure which can usually be recognized by an experienced pathologist as the result of a preceding acute atrophic process.

The course of the disease is usually marked by remissions and exacerbations with gradually increasing failure of function. Varying degrees of jaundice are usually present and an elevated temperature commonly accompanies exacerbations. Ascites is a relatively late manifestation. Various therapeutic measures are ordinarily less effective in restoring liver competence than they are in cases of the more common alcoholic cirrhosis. Therapy consists more or less in limitation of activity, depending upon the stage of the disease, the provision of an adequate diet and specific replacements. The condition tends to be one of relentless progression with eventual and complete liver failure. Esophageal varices may occur late in the disease, and gross hemorrhage from this source may necessitate consideration of surgical intervention.

One therapeutic measure should be watched with interest. In a few instances ACTH has been employed in the earlier stages of the disease with apparent interruption of the process and an improvement in symptoms and hepatic functions. ACTH must be used only with great caution inasmuch as the tendency of this preparation to cause increased proteolysis and sodium retention may readily produce unfavorable complications. With very adequate supervision, however, it is conceivable that the cellular changes accompanying the morbid conditions terminating in post atrophic cirrhosis may be halted or modified to an important degree by the careful use of this or similar substances.

### Laennec's Cirrhosis (Portal Cirrhosis, Alcoholic Cirrhosis)

This condition is by far the most common form of chronic liver disease throughout the world. The causative factors are undoubtedly multiple, but it is highly probable that the initial changes in the liver may be assigned to nutritional deficiency as a primary etiological factor. That such can be the case is evident from the careful studies of Gillman and Gillman and many others on infants and children developing full blown and often fatal cirrhosis in association with striking dietary lack. The complete reversibility of the process in early cases by the use of well balanced diets alone, further strengthens such a conception. Instances of chronic degenerative liver disease apparently caused by dietary deficiency have gradually been multiplied in various parts of the world and bear close resemblance to the results obtained by animal experimentation in which specific deficiencies in such substances as methionine, choline, and total protein have produced analogous changes. In adult human beings, additional factors undoubtedly play an important role. It is still highly controversial whether alcohol as such is a causative factor in the production of portal cirrhosis. It is undoubtedly true that a large percentage of adult cases of Laennec's cirrhosis have never used alcohol in any form. Nevertheless alcohol may act as a causative factor and when used to excess usually is accompanied by an inadequate intake of protein and total calories. Certainly intercurrent infections may play an additional role in the presence of prolonged undernutrition. Chronic diarrhea due to such conditions as chronic ulcerative

colitis or chronic dysentery may provide the background for malnutrition and hyperthyroidism of long duration and severe grade may increase metabolic activity to such an extent that the dietary intake may be quite inadequate In any event it is safe to say that the most common single factor that can be observed in patients with portal cirrhosis is that of an inadequate diet with a particular deficiency in protein and lipotropic substances The important implication of and relatively few lobules of normal parenchymal tissue The early stages may be open to controversy The so-called fatty liver may represent the initial phase of this type of liver disease although this is not at all sure In the fatty liver the liver lobules characteristically contain large numbers of polygonal cells filled with fat droplets of varying size Little or no degenerative change may be found It is possible that a continuation or frequent repetition of this

FIG 210 —Fatty infiltration Cellular degeneration Connective tissue proliferation Recovery from the effects of alcohol (biopsy of human liver) (Connor courtesy of Am J Path )

these considerations is that the disease process should be a relatively reversible one in the early stages if an adequate diet is provided

The pathological changes characteristic of Laennec's cirrhosis are those of a gradually progressive degenerative disease with more orderly processes of repair than those usually encountered in post atrophic cirrhosis The late stages may be essentially identical with the production of a hobnailed liver and histological changes *showing striking fibrosis* process may result in necrosis of individual cells in increasing numbers with repair and eventually accompanying fibrosis and scar-tissue formation During the course of portal cirrhosis the processes of hepatic-cell degeneration fatty infiltration and at times the tremendous outpouring of leukocytes into areas of necrosis are constantly recurring events Connective-tissue proliferation may involve the capsule of the liver the portal areas and the central areas of the lobules including the central veins

fat from the polygonal cells with the clearing up of an active degenerative process and with associated adequate repair of damage Obviously complete reversal of the degenerative process can be obtained only in very early cases It should be emphasized that not infrequently very early manifestations of hepatic degeneration may be extremely acute with fever jaundice right upper-quadrant pain and even ascites Under these conditions profound changes in the liver parenchyma are present which may be almost completely restored to normal by appropriate intensive therapy In the acute manifestations of the disease the use of intravenous injections of hypertonic glucose may be very effective for a few days until the patient can take an adequate diet by mouth The anemia that is a rather constant accompaniment of the later stages of the disease responds very poorly to massive doses of either iron or liver Transfusions are frequently of help as a symptomatic measure and are absolutely essential when active bleeding from varicosities has occurred When ascites is encountered and is of recent origin dietary measures plus the use of a low sodium intake are frequently effective In most resistant cases help may be obtained by the use of mercurial diuretics with or without the preceding use of ammonium chloride or similar preparations Where ascites tends to recur as a result of exacerbations of the underlying process or because of intercurrent infection it may prove to be relatively intractable but may respond temporarily if a low serum albumin is raised by the intravenous infusion of human salt free serum albumin This is an extremely expensive maneuver and in itself offers only transient help When ascites is present it is wise not to remove the accumulated abdominal fluid by paracentesis unless the volume of fluid is so great as to interfere with eating or is the cause of intolerable abdominal discomfort It is much wiser as a rule to attempt all possible medical measures before resorting to paracentesis In the later irreversible stages of the disease at times the only effective measure is that of repeated abdominal taps but under such circumstances it is obvious that the disease is far advanced in its course As an aid to the maintenance of low sodium levels the use of, ion-exchange resins may be of help It should be remembered however that they can be employed only under careful supervision and with the knowledge that they may result in a sharp reduction in sodium or potassium to a point where symptoms arise from this fact alone The recent introduction of cation-exchange resins fortified with potassium may make it possible to obviate the danger of producing sudden hypopotassemia

As already noted the development of portal hypertension results in the eventual production of engorged venous channels particularly in the form of esophageal varices and internal hemorrhoidal veins Massive bleeding may occur from either of these sources but dangerous bleeding is rarely encountered from the latter In recent years the performance of anastomotic shunts between the splenic or portal veins and the systemic circulation has given promise of an important source of protection against exsanguinating hemorrhage from these sources The work of Blakemore and of Linton during recent years has produced convincing evidence that splenorenal and portocaval shunts are of immense value when performed in carefully selected cases by extremely competent surgeons The danger of such surgery is obvious and the contraindications are clear Patients with active disease as evidenced by the presence of jaundice fever or intractable ascites probably are poor subjects for such a procedure When serum albumin values are below a level of 3 0 grams per cent the risk is very great and operation should be avoided unless there is improvement under routine intensive medical therapy If the development of ascites is of recent occurrence and follows a major hemorrhage medical measures may restore the liver to good compensation the albumin level may rise and at that point operation may properly be performed The operation should not be attempted except by adequately trained surgeons An important safeguard to the success of the operation is the employment of absolutely fresh whole blood during the operative procedure

The occurrence of acute exsanguinating

In compensated cases fatty infiltration of the parenchymal cells is frequently lacking In the late stages of the disease fibrosis predominates with a steady and marked reduction of the islands of polygonal cells, which may be subdivided into small compartments by the encroachment of connective tissue Compression of portal vein radicles is an obvious result with the development of extreme degrees of portal hypertension and enlargement of esophageal and frequently, gastric veins

Physical findings will depend entirely on the stage of the disease In the earlier stages, the liver is large and firm The edge of the liver is rounded, and the spleen typically shows only moderate increase in size Except in what might be called an active stage of the degenerative process, jaundice is lacking and hepatic tenderness is absent As reparative processes are less effective and fibrosis increases the liver typically becomes smaller and harder the spleen continues to enlarge and portal hypertension becomes evident by the appearance of a collateral circulation which can be visualized in the abdominal wall and over the lower thorax Ascites may appear but, under proper management may be only a temporary phenomenon It may be preceded by the appearance of peripheral edema which at times is incorrectly treated as evidence of cardiac or renal failure Spider angiomata appear in groups over the face, thorax, and upper extremities Bleeding may occur from the gums or the nose, from dilated veins in either the esophagus or the stomach or from internal hemorrhoids Intermittent short episodes of fever and abdominal pain may be encountered from time to time

The diagnosis will be made on the basis of a history of chronic alcoholism or dietary deficiency, or both plus the evidence of hepatic damage as manifested by the various symptoms and signs that have already been discussed In advanced cases even in the absence of bleeding it is always of importance to give the patient a swallow of barium in order to determine the presence or absence of esophageal varices Deviations from normal in all the tests of hepato cellular function may be encountered and the degree of abnormality will depend entirely upon the stage of the disease In cases of fatty liver and in the very early stages of portal cirrhosis there may be little or no abnormality in the results of tests of hepatic function, except possibly in the retention of bromsulphalein Subsequently, more and more laboratory evidence of hepatic insufficiency can be obtained The presence of jaundice hypoprothrombinemia which does not respond to the administration of vitamin K and a slow, progressive drop in serum albumin are always bad prognostic signs The finding of esophageal varices obviously suggests the possibility that fatal hemorrhage may occur at any time, regardless of the state of the liver

*Treatment* —The therapeutic principles already discussed are particularly effective in the treatment of this type of liver disease Convincing evidence of this may be found in the occasional patients in whom abdominal surgery reveals a hitherto unsuspected and totally compensated hepatic cirrhosis Such a finding clearly indicates that the disease may go on for years without causing any symptoms and without receiving any particular treatment When the disease is diagnosed because of early symptoms or signs, the most important therapeutic measures are the avoidance of overfatigue and the administration of a diet adequate in calories and high in protein If the diet is well balanced all necessary vitamins will be automatically included with the possible exception of vitamin K Furthermore the ingestion of a diet high in protein insures an adequate supply of lipotropic substances such as methionine and choline Avoidance of overactivity with resulting fatigue and the provision of an adequate diet, therefore constitute the cornerstone of therapy To this must be added the necessity of avoiding specific hepatotoxins The use of alcohol should be regarded with suspicion and probably should be completely prohibited Even in cases in which jaundice and ascites are present intensive and continuous therapy will frequently result in disappearance of these conditions restoration of liver function and the production of a compensated cirrhosis Serial liver biopsies have demonstrated conclusively that these measures are effective in promoting the disappearance of

be distinctly abnormal and disturbances of hepatocellular function may be completely absent. Later parenchymal-cell damage will obviously be associated with abnormalities of hepatocellular function.

*Treatment* is primarily surgical and whenever possible, attempts should be made to provide adequate drainage of the external biliary ducts either by removal of the obstruction or by plastic measures providing a new communication of the dilated common duct to the duodenum or jejunum. In this particular group of patients there is little doubt that the careful use of antibiotics, particularly chloromycetin and possibly aureomycin, may be effective in controlling episodes of cholangitis with chills, fever and pain. Under such treatment fever may disappear and the enlarged and tender liver may become somewhat reduced in size and completely or relatively insensitive to palpation. Antibiotic therapy is a proper protective measure preliminary to operation. In the rare event that the disease progresses to the point of massive hemorrhage from esophageal varices, shunt surgery can be considered and has on occasion been successfully performed.

CHOLANGIOLITIC BILIARY CIRRHOSIS.— This extremely rare condition differs from obstructive biliary cirrhosis in that the evidences of obstruction are entirely confined to the internal structure of the liver. It occurs in younger adults. The etiology is not known.

*Morbid Anatomy*.—Pathological changes are initially limited to the bile canaliculi which show evidences of cholangitis or pericholangitis with bile stasis. As the disease progresses degenerative changes may occur in the parenchyma with consequent repair and fibrosis. Enlargement of the liver and spleen is pronounced. The external bile ducts are essentially normal.

*Symptoms and Signs*.—The initial symptoms are variable. They may be similar to those of infectious hepatitis or they may be characterized by a series of attacks of fever, jaundice and right upper-quadrant pain with enlargement of the liver and spleen. Occasionally the only presenting symptom is intense itching which may persist for many months before the occurrence of jaundice is noted. Once the disease is well established pruritis is a rather constant and very distressing symptom. The late stages of the disease may be accompanied by evidences of hepatic insufficiency and by the development of portal hypertension. An interesting but rare complication of this condition as well as that of obstructive biliary cirrhosis is the gradual decalcification of the bony structure with spontaneous fractures. In spite of the typical and persistent appearance of jaundice the stools usually contain moderate amounts of bile pigment and may be of almost normal color. Except in the late stages of the disease laboratory examinations reveal evidences of disturbed excretion of bile products. Alkaline phosphatase and serum cholesterol may reach very high levels. As in other chronic forms of liver disease clubbing of the fingers is occasionally seen. The jaundice tends to be a dark brown or greenish jaundice and the skin frequently becomes extremely dark due to deposition of melanin. Xanthomata are frequently present around the eyes and in the flexures of the skin of the hands, elbows and knees; they may be very painful.

The disease progresses slowly but is usually fatal within a period of from eight to ten years. Except for supportive measures therapy is largely symptomatic. When itching is extreme experience has shown that prolonged T tube drainage of the common duct may result in considerable relief of this symptom. An interesting fact is that such drainage may also be accompanied by the complete disappearance of the xanthomata.

The term *Hanot's cirrhosis* has been loosely applied to this condition and occasionally to that of obstructive biliary cirrhosis. Any exact definition of Hanot's cirrhosis based on his original article is absolutely impossible and the term should be avoided.

SYPHILITIC CIRRHOSIS (HEPAR LOBATUM)

True syphilitic cirrhosis is a manifestation of late acquired syphilis and is the result of gummatous involvement with fibrosis and the production of coarse lobulation of the organ. With earlier diagnosis and improved methods of treatment this manifestation of

bleeding from esophageal varices in itself constitutes a serious acute emergency If bleeding does not stop spontaneously within a reasonable period of time, compression of the coronary veins by tamponade with an inflated balloon may be a life saving procedure The actual ligation of bleeding varices has been successfully performed in a few instances by the transthoracic surgical approach When hematemesis from esophageal varices occurs oral feeding should be avoided for several days in contradistinction to the use of small frequent feedings that may properly be employed in instances of hemorrhage from diffuse gastritis or peptic ulcer Obviously blood lost by bleeding from varices must be replaced

One final consideration is the treatment of intermittent episodes of fever having no other determinable cause than the presence of cirrhosis In a few cases the use of chloromycetin over a period of several days has adequately controlled febrile episodes and has definitely improved the condition of the patient

*Course* —As already implied the course of the disease is variable but it may progress over a period of very many years With a newer understanding of the principles of treatment of hepatic disease it is important to adopt an optimistic attitude and employ intensive dietary and replacement measures until any evidence of a response is lacking It will frequently be a matter of surprise to the physician that such measures will restore an obvious cirrhotic to many months or years of useful living

## Biliary Cirrhosis

Obstructive Biliary Cirrhosis —Obstructive biliary cirrhosis is a condition which develops as a result of chronic partial obstruction and infection of the large bile ducts It is relatively uncommon It is usually encountered as a result of surgical trauma to the common bile duct or in patients with common duct stone of long standing It may result from a slowly progressing constriction of the duct by surrounding adhesions, enlarged lymph glands or carcinoma, occasionally, it is the result of parasitic infestation It has been produced experimentally in animals by ligation of the common duct Whether it is due to mechanical obstruction alone, with associated back pressure in the ductal system or is caused by ductal infection which is almost invariably present, is not clear, both factors are probably operative

*Morbid Anatomy* —Unlike post atrophic cirrhosis and portal cirrhosis the liver in biliary cirrhosis is characterized by a relatively smooth surface which, on close inspection, is found to be finely granular and deeply pigmented with biliverdin The chief histological characteristics are those of striking increase in connective tissue involving the capsule and the portal areas, with interlobular extension, and by dilatation and proliferation of the bile ducts Bile stasis is usually recognized by the appearance of masses of inspissated bile in the dilated canaliculi In the advanced stages of the disease changes in the parenchymal cells occur and eventually the processes of polygonal-cell degeneration repair and fibrosis become apparent

*Symptoms and Signs* —The disease is most commonly encountered in the later decades of life, and there is usually a definite story of intermittent obstruction of many years duration with episodes of fever chills jaundice and right upper-quadrant pain Frequently initial symptoms closely follow operation on the gallbladder or common bile duct As the disease progresses anorexia nausea and vomiting may be present, and easy fatigability is common Fat loss may occur and spontaneous bleeding due to hypoprothrombinemia is encountered In advanced cases all the evidences of liver insufficiency are present and ascites and peripheral edema are to be expected Hemorrhage from esophageal varices occurs if the patient survives the disease for a period of time sufficient to produce fibrosis and portal hypertension Hepatic enlargement is relatively marked and an increase in the size of the spleen can practically always be demonstrated on careful examination Jaundice is nearly always present Laboratory findings as might be expected vary with the stage of the disease In the earlier stages those tests indicating interference with the excretion of bile and other substances will

along with other signs of cardiac insufficiency Pathologically the liver is enlarged and the capsule tense On section a reddish-gray mottling with a typical nutmeg appearance is seen Central necrosis and hemorrhage are present in severe cases Liver functions, as measured by laboratory tests are abnormal in direct relation to the degree of cardiac failure In most instances the process is entirely reversible if cardiac insufficiency can be corrected

*Acute thrombosis of the portal vein* is fortunately very uncommon It may occur in association with cirrhosis of the liver as a rare complication It may be associated with malignant disease which causes thrombosis by compression of the vein It may be secondary to an adjacent inflammatory process or may result from a specific infection such as typhoid It occurs as a fulminating incident leading to severe abdominal pain splenic enlargement ascites and hemorrhage from the upper gastrointestinal tract Fever and a striking leukocytosis are usually encountered Death may occur in a few days due to extension of the thrombotic process to the mesenteric veins

Diagnosis of the acute form of the disease is extremely difficult especially when there is a coexisting cirrhosis of the liver In the absence of a known cirrhotic process the sudden appearance of the symptoms described above together with the rapid development of signs of portal vein obstruction may give a clue to the primary underlying process

Treatment of the acute condition is usually ineffective but measures to control shock and proper use of antibiotics would seem to be indicated

*Chronic thrombosis of the portal vein* may occur without any diagnostic symptoms or signs until portal or splenic vein hypertension has developed One may be able to elicit a history of recurrent episodes of vague abdominal pain and fever following acute infections such as typhoid malaria pneumonia and the like Occasionally there may be a history of an omphalitis in infancy The process is essentially an infective thrombophlebitis of the portal vein or its radicles with resulting cavernomatous changes and at times chronic fibrosis and occlusion Evidences of a collateral circulation gradually appear with enlargement of the spleen and anemia Hemorrhage from dilated esophageal or gastric veins may be the first indication of the condition The entire symptom complex may properly be classified as Banti s disease or congestive splenomegaly Hepatic changes as a rule are minor except where a progressive cirrhotic process is associated with an active thrombophlebitis of the portal venous system Where cirrhosis is not the primary disease changes in the liver consist essentially of minor degrees of degeneration of hepatic lobules with fibrosis and diminution in the size of the organ No serious alterations in hepatic function occur If there is bleeding from esophageal varices serious consideration should be given to the possibility of adequate venous shunt surgery with a resulting reduction in portal venous pressure

*Thrombosis of the Hepatic Veins* (Budd-Chiari Syndrome) —Thrombosis of the hepatic veins is a rare condition which occurs as a result of inflammatory neoplastic or fibrotic changes in the liver or in the course of such diseases as thrombophlebitis migrans and polycythemia vera As in thrombosis of the portal vein, acute and chronic forms of the condition may be encountered Obstruction of the hepatic veins may be partial or complete Hepatic changes depend upon the completeness of the occluding process There may be marked engorgement of the liver with dilatation of the sinusoids Hemorrhages in the region of the central veins may be prominent with necrosis of the lobular tissue Acute thrombosis of the hepatic veins is accompanied by the sudden appearance of epigastric pain rapid enlargement of the liver ascites and collateral venous engorgement Fever and leukocytosis are present Because of the rapid enlargement of the liver right upper-quadrant abdominal tenderness is usually present Enlargement of the collateral veins may be extensive Jaundice is not a striking feature As a rule the condition progresses steadily with increasing impairment of hepatic function and death within a few weeks

Chronic partial thrombosis of the hepatic veins undoubtedly occurs but diagnosis of

syphilis is becoming progressively less common and, at present, is only occasionally encountered. The exact identity of hepar lobatum is controversial, and it is frequently the case that gummatous involvement of the liver, with subsequent healing, may occur in association with portal cirrhosis. In cases *in which a very grossly lobulated liver is* encountered in patients with positive serological evidence of syphilis, the diagnosis of hepar lobatum may be justified, although one is never certain that the obvious liver involvement is due solely to spirochetal disease. In the absence of evidence of diffuse liver disease with failure, such treatment should be carried out as is commonly employed in the presence of gummatous lesions. When evidences of *liver insufficiency* are present, careful supportive measures and proper replacement therapy should also be employed.

### Cardiac Cirrhosis

This condition is characterized by fibrotic changes in the liver, changes primarily localized around the central hepatic veins. It is always associated *with long standing congestive* heart failure. This may be secondary to tricuspid insufficiency, marked mitral involvement, or chronic constrictive pericarditis. Other forms of heart disease may occasionally provide the basis for the appearance of pronounced structural hepatic changes.

*Morbid Anatomy.*—On gross examination, the liver may be found to be normal in size or slightly *enlarged*. It is firm, finely nodular, and darkly mottled in color. Extensive fibrosis is evident on cut section, and histological examination shows the central areas of the lobule to be most involved, although connective tissue increase may be apparent in the portal areas as well.

*Diagnosis.*—The diagnosis is never justified unless evidences of long standing congestive failure are clear. Signs of cardiac failure are obvious, cyanosis usually being present. When associated with constrictive pericarditis, liver enlargement is usually more marked than when due to other causes of cardiac failure. Splenic enlargement is nearly always present, and engorgement of the neck veins can always be demonstrated. Ascites may be present. Laboratory tests reveal abnormalities in hepatocellular function. Jaundice is rarely present.

*Treatment* of the hepatic disease consists almost exclusively in measures directed toward improvement of the cardiac condition. Restriction of sodium in the diet is an important measure. In constrictive pericarditis, surgical decortication of the heart may *be associated with surprising improvement* in hepatic function, but it is obvious that no therapeutic measure can produce complete regression of the fibrotic process in the liver.

### Parasitic Cirrhosis

Parasitic cirrhosis of the liver is an important complication of infestation by various liver flukes, such as those encountered in *distosomiasis and schistosomiasis*. These diseases are adequately discussed in another section. In the chronic, advanced forms of liver disease secondary to liver flukes, the general principles underlying the evaluation and treatment of chronic hepatic disorders obtain.

Hemochromatosis.—Hepatic changes in hemochromatosis have been described under *Diseases of Metabolism*. It is pertinent to point out that enlargement of the liver may be the only clinical manifestation of this unusual disturbance in iron metabolism. Laboratory evidence of impairment of liver function may be obtained, but in no way indicates the cause of the hepatomegaly. Aspiration biopsy of the liver will invariably *provide the basis for a histological diagnosis* of the disease.

## DISTURBANCES OF HEPATIC CIRCULATION

Congestive Heart Failure.—Congestive heart failure almost invariably leads to transient and usually reversible hepatic changes. If the congestive failure is of extreme degree and of long standing, it may result in a true fibrotic process which *has* already been described as cardiac cirrhosis. *The usual manifestations of congestive* failure are those of slight hepatic enlargement, frequently with tenderness over the liver

along with other signs of cardiac insufficiency Pathologically the liver is enlarged and the capsule tense On section a reddish gray mottling with a typical nutmeg' appearance, is seen Central necrosis and hemorrhage are present in severe cases Liver functions as measured by laboratory tests are abnormal in direct relation to the degree of cardiac failure In most instances the process is entirely reversible if cardiac insufficiency can be corrected

*Acute thrombosis of the portal vein* is fortunately very uncommon It may occur in association with cirrhosis of the liver as a rare complication It may be associated with malignant disease which causes thrombosis by compression of the vein It may be secondary to an adjacent inflammatory process or may result from a specific infection such as typhoid It occurs as a fulminating incident leading to severe abdominal pain splenic enlargement ascites and hemorrhage from the upper gastrointestinal tract Fever and a striking leukocytosis are usually encountered Death may occur in a few days due to extension of the thrombotic process to the mesenteric veins

Diagnosis of the acute form of the disease is extremely difficult especially when there is a coexisting cirrhosis of the liver In the absence of a known cirrhotic process the sudden appearance of the symptoms described above together with the rapid development of signs of portal vein obstruction may give a clue to the primary underlying process

Treatment of the acute condition is usually ineffective but measures to control shock and proper use of antibiotics would seem to be indicated

*Chronic thrombosis of the portal vein* may occur without any diagnostic symptoms or signs until portal or splenic vein hypertension has developed One may be able to elicit a history of recurrent episodes of vague abdominal pain and fever following acute infections such as typhoid malaria pneumonia and the like Occasionally there may be a history of an omphalitis in infancy The process is essentially an infective thrombophlebitis of the portal vein or its radicles with resulting cavernomatous changes and at times chronic fibrosis and occlusion Evidences of a collateral circulation gradually appear with enlargement of the spleen and anemia Hemorrhage from dilated esophageal or gastric veins may be the first indication of the condition The entire symptom complex may properly be classified as Banti s disease or congestive splenomegaly Hepatic changes as a rule are minor except where a progressive cirrhotic process is associated with an active thrombophlebitis of the portal venous system Where cirrhosis is not the primary disease changes in the liver consist essentially of minor degrees of degeneration of hepatic lobules with fibrosis and diminution in the size of the organ No serious alterations in hepatic function occur If there is bleeding from esophageal varices serious consideration should be given to the possibility of adequate venous shunt surgery with a resulting reduction in portal venous pressure

*Thrombosis of the Hepatic Veins* (Budd Chiari Syndrome) —Thrombosis of the hepatic veins is a rare condition which occurs as a result of inflammatory, neoplastic or fibrotic changes in the liver or in the course of such diseases as thrombophlebitis migrans and polycythemia vera As in thrombosis of the portal vein acute and chronic forms of the condition may be encountered Obstruction of the hepatic veins may be partial or complete Hepatic changes depend upon the completeness of the occluding process There may be marked engorgement of the liver with dilatation of the sinusoids Hemorrhages in the region of the central veins may be prominent with necrosis of the lobular tissue Acute thrombosis of the hepatic veins is accompanied by the sudden appearance of epigastric pain rapid enlargement of the liver ascites and collateral venous engorgement Fever and leukocytosis are present Because of the rapid enlargement of the liver right upper quadrant abdominal tenderness is usually present Enlargement of the collateral veins may be extensive Jaundice is not a striking feature As a rule the condition progresses steadily with increasing impairment of hepatic function and death within a few weeks

Chronic partial thrombosis of the hepatic veins undoubtedly occurs but diagnosis of

syphilis is becoming progressively less common and, at present, is only occasionally encountered The exact identity of hepar lobatum is controversial, and it is frequently the case that gummatous involvement of the liver, with subsequent healing, may occur in association with portal cirrhosis In cases in which a very grossly lobulated liver is encountered in patients with positive serological evidence of syphilis, the diagnosis of hepar lobatum may be justified, although one is never certain that the obvious liver involvement is due solely to spirochetal disease In the absence of evidence of diffuse liver disease with failure such treatment should be carried out as is commonly employed in the presence of gummatous lesions When evidences of liver insufficiency are present, careful supportive measures and proper replacement therapy should also be employed

## Cardiac Cirrhosis

This condition is characterized by fibrotic changes in the liver changes primarily localized around the central hepatic veins It is always associated with long standing congestive heart failure This may be secondary to tricuspid insufficiency marked mitral involvement or chronic constrictive pericarditis Other forms of heart disease may occasionally provide the basis for the appearance of pronounced structural hepatic changes

*Morbid Anatomy* —On gross examination the liver may be found to be normal in size or slightly enlarged It is firm finely nodular and darkly mottled in color Extensive fibrosis is evident on cut section and histological examination shows the central areas of the lobule to be most involved although connective tissue increase may be apparent in the portal areas as well

*Diagnosis* —The diagnosis is never justified unless evidences of long standing congestive failure are clear Signs of cardiac failure are obvious, cyanosis usually being present When associated with constrictive pericarditis, liver enlargement is usually more marked than when due to other causes of cardiac failure Splenic enlargement is nearly always present, and engorgement of the neck veins can always be demonstrated Ascites may be present Laboratory tests reveal abnormalities in hepatocellular function Jaundice is rarely present

*Treatment* of the hepatic disease consists almost exclusively in measures directed toward improvement of the cardiac condition Restriction of sodium in the diet is an important measure In constrictive pericarditis, surgical decortication of the heart may be associated with surprising improvement in hepatic function, but it is obvious that no therapeutic measure can produce complete regression of the fibrotic process in the liver

## Parasitic Cirrhosis

Parasitic cirrhosis of the liver is an important complication of infestation by various liver flukes such as those encountered in distosomiasis and schistosomiasis These diseases are adequately discussed in another section In the chronic, advanced forms of liver disease secondary to liver flukes the general principles underlying the evaluation and treatment of chronic hepatic disorders obtain

Hemochromatosis —Hepatic changes in hemochromatosis have been described under *Diseases of Metabolism* It is pertinent to point out that enlargement of the liver may be the only clinical manifestation of this unusual disturbance in iron metabolism Laboratory evidence of impairment of liver function may be obtained but in no way indicates the cause of the hepatomegaly Aspiration biopsy of the liver will invariably provide the basis for a histological diagnosis of the disease

# DISTURBANCES OF HEPATIC CIRCULATION

Congestive Heart Failure —Congestive heart failure almost invariably leads to transient and usually reversible hepatic changes If the congestive failure is of extreme degree and of long standing it may result in a true fibrotic process which has already been described as cardiac cirrhosis The usual manifestations of congestive failure are those of slight hepatic enlargement frequently with tenderness over the liver

along with other signs of cardiac insufficiency Pathologically, the liver is enlarged and the capsule tense On section a reddish gray mottling with a typical nutmeg appearance, is seen Central necrosis and hemorrhage are present in severe cases Liver functions as measured by laboratory tests are abnormal in direct relation to the degree of cardiac failure In most instances the process is entirely reversible if cardiac insufficiency can be corrected

*Acute thrombosis of the portal vein* is fortunately very uncommon It may occur in association with cirrhosis of the liver as a rare complication It may be associated with malignant disease which causes thrombosis by compression of the vein It may be secondary to an adjacent inflammatory process or may result from a specific infection such as typhoid It occurs as a fulminating incident leading to severe abdominal pain splenic enlargement, ascites and hemorrhage from the upper gastrointestinal tract Fever and a striking leukocytosis are usually encountered Death may occur in a few days due to extension of the thrombotic process to the mesenteric veins

Diagnosis of the acute form of the disease is extremely difficult especially when there is a coexisting cirrhosis of the liver In the absence of a known cirrhotic process the sudden appearance of the symptoms described above together with the rapid development of sign of portal vein obstruction may give a clue to the primary underlying process

Treatment of the acute condition is usually ineffective but measures to control shock and proper use of antibiotics would seem to be indicated

*Chronic thrombosis of the portal vein* may occur without any diagnostic symptoms or signs until portal or splenic vein hypertension has developed One may be able to elicit a history of recurrent episodes of vague abdominal pain and fever following acute infections such as typhoid malaria pneumonia and the like Occasionally there may be a history of an omphalitis in infancy The process is essentially an infective thrombophlebitis of the portal vein or its radicles with resulting cavernomatous changes and at times chronic fibrosis and occlusion Evidences of a collateral circulation gradually appear with enlargement of the spleen and anemia Hemorrhage from dilated esophageal or gastric veins may be the first indication of the condition The entire symptom complex may properly be classified as Banti s disease or congestive splenomegaly Hepatic changes as a rule are minor except where a progressive cirrhotic process is associated with an active thrombophlebitis of the portal venous system Where cirrhosis is not the primary disease changes in the liver consist essentially of minor degrees of degeneration of hepatic lobules with fibrosis and diminution in the size of the organ No serious alterations in hepatic function occur If there is bleeding from esophageal varices serious consideration should be given to the possibility of adequate venous shunt surgery with a resulting reduction in portal venous pressure

*Thrombosis of the Hepatic Veins* (Budd Chiari Syndrome) —Thrombosis of the hepatic veins is a rare condition which occurs as a result of inflammatory neoplastic or fibrotic changes in the liver or in the course of such diseases as thrombophlebitis migrans and polycythemia vera As in thrombosis of the portal vein acute and chronic forms of the condition may be encountered Obstruction of the hepatic veins may be partial or complete Hepatic changes depend upon the completeness of the occluding process There may be marked engorgement of the liver with dilatation of the sinusoids Hemorrhages in the region of the central veins may be prominent with necrosis of the lobular tissue Acute thrombosis of the hepatic veins is accompanied by the sudden appearance of epigastric pain rapid enlargement of the liver ascites and collateral venous engorgement Fever and leukocytosis are present Because of the rapid enlargement of the liver right upper quadrant abdominal tenderness is usually present Enlargement of the collateral veins may be extensive Jaundice is not a striking feature As a rule the condition progresses steadily with increasing impairment of hepatic function and death within a few weeks

Chronic partial thrombosis of the hepatic veins undoubtedly occurs but diagnosis of

the condition is rarely possible prior to death It may be suspected in cases in which there is hepatic enlargement or extensive collateral circulation and intractable ascites, without evidence of splenic enlargement There is no satisfactory treatment of either the acute or the chronic type of the disease

HEPATOLENTICULAR DEGENERATION (WILSON'S DISEASE) —This curious combination of lenticular degeneration of the brain and portal cirrhosis is extremely rare It tends to occur in families and becomes apparent in the early decades of life Evidences of liver impairment vary considerably in individual cases and the course of the disease follows the usual pattern of portal cirrhosis There is some suggestion that disturbances in copper metabolism may be involved in the production of the condition, which has been more fully discussed under *Organic Diseases of the Nervous System* When symptoms of liver impairment are present general measures already discussed may be employed As a rule, they are relatively ineffective

TUMORS OF THE LIVER —Tumors of the liver include benign cysts benign cellular tumors, primary carcinoma and metastatic carcinoma

*Benign cysts of the liver* are not productive of symptoms and are diagnosed only at operation for some other condition The origin of such cysts is not known and no therapy is indicated Hepatic cysts may occur in association with cystic disease of the kidneys Echinococcus disease is a common cause of cysts in the liver and has been discussed in the section on *Metazoan Diseases*

*Benign cellular tumors of the liver* are uncommon and comprise benign adenomata and hemangiomata Neither type of tumor produces symptoms or interference with hepatic function The diagnosis is usually made by accident at the time of abdominal exploration Bleeding following trauma may occur from hepatic hemangiomata

*Primary carcinoma of the liver* is of two types (1) liver-cell carcinoma (primary hepatoma) and (2) duct cell carcinoma (cholangioma) The liver cell carcinoma is much more common than that arising from the bile ducts Primary hepatoma may occur in the absence of other disease of the liver but it is usually associated with portal cirrhosis or with the types of cirrhosis that are manifestations of infestation by liver flukes

It is relatively common in certain Asiatic countries and in other sections of the world where schistomiasis and distomiasis are prevalent In the United States, it is nearly always associated with portal cirrhosis of long standing It usually occurs in men over the age of fifty Duct-cell carcinoma is more frequently seen in women and may appear as a late manifestation of long standing cholangitis or biliary cirrhosis

Symptoms of primary carcinoma of the liver do not differ significantly from those of the underlying cirrhosis The existence of a malignant tumor may be suspected by the steady increase in size of particular areas of the liver which may occasionally become frankly nodular Jaundice may or may not be a striking feature but it usually is present and is apt to increase steadily in intensity Anorexia weakness and loss of weight occur at a rate more rapid than that expected in the natural course of the underlying cirrhotic process Abdominal or back pain may be a feature and palpation of the liver frequently demonstrates tender areas Ascites may be manifest and the ascitic fluid is frequently hemorrhagic and of high specific gravity it may also contain tumor cells Upper abdominal films may show lobulation of the liver outline Liver function tests are in no way diagnostic but aspiration biopsy of the liver may frequently provide proof of malignant disease Medical treatment is entirely palliative and attempts to resect involved areas are of dubious value

*Secondary carcinoma of the liver* is common Metastases may be derived from primary neoplasms of the esophagus, stomach pancreas colon and biliary passages Occasionally hepatic metastases are secondary to cancer of the breast Metastatic nodules may be few in number or may involve a very large proportion of the organ with compression of hepatic units and resulting necrosis intrahepatic hemorrhage and jaundice The liver may be extremely large Individual nodules may be easily felt and may be tender to palpation Splenic enlargement is extremely uncommon Ascites is frequent and the fluid like that associated with primary malignancy of the liver is usually of

high specific gravity It contains easily demonstrable red cells and occasionally malignant cells Involvement of the liver may on rare occasions be so extreme as to produce portal hypertension and esophageal varices with bleeding

The symptoms associated with metastatic malignancy of the liver are those of the primary disease plus those associated with focal or diffuse liver involvement Liver function tests may yield entirely normal results or results notably deranged due to very extensive involvement of the organ Hitherto unsuspected neoplasia may be *diagnosed from histological study of the* material obtained by *punch biopsy* of the liver Therapy is almost entirely palliative in nature On rare occasions when abdominal exploration has revealed solitary implants of metastatic disease in the liver radical resection may be justified and may retard the course of the disease

Abscess of the Liver —Abscess of the liver may be due to parasitic infestation by Entameba histolytica or may be secondary to extra hepatic pyogenic infection The hepatic manifestations of amebiasis have been discussed *in the section on Protozoan Disease* Pyogenic abscess of the liver is usually associated with suppurative processes secondary to appendicitis cholelithiasis and cholecystitis It may occur as a result of systemic infection or by direct association with a penetrating wound Occasionally amebic abscesses become infected with pyogenic organisms The causative factor is usually E coli or a Gram positive coccus Infection may reach the liver by way of the portal vein it may ascend by way of the hepatic ducts or may be brought to the *liver through the hepatic artery* Liver abscesses are usually multiple

*Symptoms* —Pyogenic infection of the liver with abscess formation is characterized by a septic type of temperature accompanied by shaking chills profuse sweating and extreme weakness Nausea and vomiting may occur In severe cases abdominal distention with adynamic ileus is present *The liver may be moderately enlarged* and is nearly always tender to palpation Indeed the most characteristic sign is that of pain produced by bimanual compression of the lower right thorax Jaundice may occur but may be completely absent Ascites may be noted in severe cases especially in those associated with pylephlebitis The facial expression of the patient is drawn and gives evidence of fatigue and prostration Marked leukocytosis is to be expected

*Diagnosis* is always to be suspected in the presence of a septic temperature hepatic enlargement and tenderness and a recent story of appendicitis or cholecystitis The condition often follows operation for the above diseases Although the diagnosis is usually made on clinical grounds confirma*tion of the condition may be obtained in rare* instances by *radiological studies* of the liver after the intravenous injection of thorotrast Such an examination may reveal discrete punched out areas in the liver

*Treatment* —The outlook is always extremely grave but intensive chemotherapy and the use of antibiotics has undoubtedly modified the course of the condition Surgical drainage of single or multiple large abscesses may be possible but the intensive use of sulfadiazine penicillin and streptomycin is an indispensable therapeutic measure

## DISEASES OF THE GALLBLADDER AND BILE DUCTS

Pathological conditions involving the gallbladder and bile ducts are primarily associated with inflammatory disease Benign or malignant tumors may occur but are relatively very uncommon Infection of the gallbladder may occur in the course of other infectious disease such as typhoid fever or it may appear without known etiology In *the vast majority of instances* inflammation of the gallbladder and ducts is secondary to the presence of biliary calculi Symptoms result from the presence of local inflammation and from interference with the normal flow of bile from the gallbladder or the external hepatic ducts or common bile duct In addition to evidences of infection cholecystic and choledochal disease are usually accompanied by pain referred to the right upper abdominal quadrant or to the epigastrium with radiation to the right subscapular area or to the mid back The

appearance of jaundice is a variable finding. It may be completely absent, or it may be intense because of almost complete obstruction to the flow of bile into the duodenum. Wherever any *degree of obstruction* exists in the ductal system, infection is invariably present.

Tests of gallbladder function can be made by cholecystography following the oral administration of tetraiodophenolphthalein. This dye is absorbed into the portal circulation and excreted almost completely in the bile. When the gallbladder is normal or has not lost its powers of concentration because of chronic inflammatory disease and fibrosis, the dye will appear as a radio-opaque shadow, filling the entire organ. The administration of a *fat-containing meal will result* in prompt contraction of the gallbladder if function is normal. If the concentrating and contractile power of the gallbaldder has been lost by chronic disease or if a stone occludes the cystic duct, then dye will fail to reach the gallbaldder and no shadow will be noted. *Such a finding*, if confirmed by a second examination, will justify the diagnosis of nonfunctioning gallbladder. When stones are present in the gallbladder and concentrating function is not lost, gall stones may show as contrasting radiolucent areas, particularly if the stones are of high cholesterol content. Stones with high calcium content may be seen as very opaque shadows in the region of the gallbladder or may be actually demonstrable after cholecystography in the dye-filled organ. It is important to remember that films taken in the upright position after cholecystography may reveal a layer of translucent cholesterol stones in the fundus that were previously not demonstrable on routine horizontal films. Cholecystography provides the best means of determining gallbladder function and demonstrating biliary calculi. Another diagnostic procedure of greater difficulty and of less value is that of duodenal drainage. Material obtained during intubation of the duodenum may, on centrifugation, show microscopic evidence of cholesterol- or calcium bilirubin crystals in abundance. Such a finding in most instances gives definite indication of calculus formation. *This* method is of particular value in cases in which previous cholecystectomy has been performed and in which clinical symptoms suggest the possibility of remaining gravel or calculi in the common bile duct. In a very special group of cases duodenal drainage is of importance in determining the presence of pathogenic bacteria. In typhoid carriers, cultures *obtained by duodenal drainage are practically* always positive and diagnostic.

CHOLELITHIASIS.—Biliary calculi are commonly composed of cholesterol or calcium bilirubin, or a combination of these two elements. Rarely, gall stones may be composed solely of calcium carbonate or calcium oxylate. Stones composed entirely of bile pigment are relatively uncommon and are found only in cases of jaundice due to hemolytic disease. *With the exception of pure* pigment stones the exact etiology of gall stones is not clear. Infection may play an important role in altering the chemical and physical characteristics of bile with precipitation of crystalline material that subsequently provides the basis for calculus formation. The most obvious example of such a process is that which occurs in typhoid carriers. Almost invariably typhoid carriers who harbor the infection in the gallbladder show evidence of chronic gallbladder infection and calculus formation. Frequently viable typhoid bacilli may be found in the gall stones. Metabolic disorders such as those occurring in diabetes mellitus may provide at least a partial explanation of *calculus formation. In diabetes mellitus* disorders of lipid metabolism are common with high levels of cholesterol in the blood and bile. The very frequent occurrence of gall stones in diabetics suggests that such a relationship may be important. Similarly the factors underlying obesity may alter the concentration of *cholesterol and lipids in the* bile with resulting calculus formation. Multiple pregnancies have been considered as a possible cause of altered bile chemistry with gall-stone formation. It is probable that numerous factors influencing the concentration of one or another element of the bile *over long periods of time may be re*sponsible for calculus formation.

Biliary calculi are found in between 5 and 10 per cent of all persons coming to autopsy. They are more frequently present in women

than in men possibly due to the greater incidence of obesity and the effect of repeated pregnancies Stones may be single or multiple Large single stones are common but numerous small calculi are frequently found in the gallbladder and/or the common duct When pigment stones alone are present they occur in great numbers and are usually of very small size

*Symptoms* of cholelithiasis are usually characteristic but gall stones may be present for many years or throughout the major portion of life without producing any subjective disturbances The most characteristic symptom associated with cholelithiasis is that of biliary colic This occurs as a single episode or as frequently repeated attacks of right upper-quadrant abdominal pain However the pain may be epigastric in location or may radiate under the right scapula In rare instances biliary colic may be experienced only in the right subscapular area Occasionally the pain is experienced just below the xiphoid with radiation into the left shoulder and down the left arm completely simulating the pain of angina pectoris In very unusual cases the pain may be felt only in the left upper quadrant or in the lower abdomen The most characteristic feature of biliary colic is the fact that it usually occurs without preceding symptoms of importance gradually increases in severity then diminishes and finally disappears leaving residual tenderness in the right upper quadrant The duration of a given attack may be limited to a relatively few minutes but typically it lasts for several hours and may persist intermittently for days The pain may be relatively mild in intensity but may be so severe as to require frequent hypodermic injections of morphine for relief Nausea and vomiting are common but on numerous occasions may be secondary to the administration of morphine rather than to the underlying disease It is thought that the intake of fatty food frequently precipitates attacks of biliary colic Such a conception may be a reasonable one since the ingestion of fatty food may cause a contraction of the gallbladder It must not be forgotten however that in very many instances bladder contractility is lost because of thickening and fibrosis of the wall with obvious interference with any such pain producing mechanism Intolerance to fatty or greasy foods or to large meals and vague symptoms of "indigestion, with heartburn and belching of gas are frequently associated with cholelithiasis and are noted between attacks Whether these symptoms are secondary to biliary tract disease or to faulty dietary and bowel habits is open to question At times ulcer like symptoms are present due to reflex motor and secretory disturbances of the gastroduodenal segment In acute attacks of biliary colic fever and occasionally chills may occur but are by no means invariable

Physical signs vary extremely in individual cases The most common sign to be noted is that of focal tenderness over the region of the gallbladder Examination during an acute attack may also reveal muscle rigidity and occasionally a palpable gallbladder In the absence of jaundice the finding of a palpable gallbladder during an attack is highly suggestive of the presence of a stone temporarily impacted in the ampulla of the cystic duct with consequent obstruction to the flow of bile from the gallbladder The resulting dilatation and enlargement of the gallbladder to the point where it can be palpated may be extremely transitory this is due to the fact that the stone obstructing the cystic duct may have a ball valve action and may be shortly dislodged from its obstructing position Jaundice may occur during attacks of biliary colic as a result of one of two mechanisms It may be due to the presence of stones in the common duct causing obstruction to the flow of bile or it may be associated with cholangitis secondary to ductal obstruction or to infection spreading from the gallbladder itself In individual attacks the depth of jaundice may be relatively slight but if the attack persists with a sufficient degree of obstruction and infection jaundice may be severe and may last for days or weeks In rare instances acute abdominal pain may be due to an inflammatory process involving the peritoneum in the vicinity of the gallbladder secondary to perforation of the gallbladder or common duct As discussed under *Intestinal Obstruction* a large gall stone may penetrate the wall of the gallbladder or more rarely the

common duct and form a fistulous tract which eventually communicates with the duodenum, permitting passage of gall stones into the lumen of the intestine Intestinal obstruction from such a cause usually occurs in the vicinity of the ileocecal valve The appearance of chills in the presence of fever and biliary colic nearly always implies intrahepatic infection (cholangitis) In acute gall stone attacks leukocytosis of moderate degree is to be expected

ical studies X ray films of the right upper quadrant may reveal calcareous shadows in the region of the gallbladder and less often in the vicinity of the common duct In the absence of such findings cholecystograms should be taken, and the demonstration of calculi in the gallbladder or of a nonfilling gallbladder (carefully checked by a second similar examination) should make a definitive diagnosis In short lived attacks an additional diagnostic

Fig 211 —Calcified gallstones in gall bladder partially filled with dye

*Diagnosis* —The diagnosis of cholelithiasis is nearly always made on the basis of a good history and physical examination The distinguishing feature is the occurrence of episodic attacks of right-upper-quadrant or epigastric pain, with residual tenderness and relative freedom from important symptoms between acute attacks Such a story in an obese individual over the age of forty should immediately lead to a presumptive diagnosis of cholelithiasis and to appropriate radiolog

point may be the demonstration of increased amounts of bilirubin in the serum

*Complications* —Cholangitis or infection of the intrahepatic biliary radicles may occur usually in conjunction with common-duct stones which partially obstruct flow of bile Occasionally though not often cholangitis is associated with obstruction due to calculi in the intrahepatic ducts Perforation of the gallbladder by gall stones with the formation of a biliary fistula into the intestinal

tract has already been mentioned. Impaction of a stone in the ampulla of the cystic duct may be transitory, but if it persists, hydrops of the gallbladder will follow. If unrelieved, eventual infection with empyema of the gallbladder will occur. Partial obstruction of the common duct may persist as a chronic condition and, if unrelieved, may eventually result in early biliary cirrhosis. When obstruction of the common duct is nearly complete and is of long standing, the exclusion of bile from the duodenum may result in the production of hypoprothrombinemia of serious degree. There may be a chronic inflammatory reaction in the common duct, with a resultant stenosis that may make surgical measures extremely difficult and dangerous. In a certain number of instances a gall stone impacted in the ampulla of Vater not only may result in typical obstructive jaundice, but in addition may block the flow of pancreatic secretion to such an extent that an associated pancreatitis that will dominate the entire clinical picture may occur.

*Differential Diagnosis.*—Although the diagnosis of cholelithiasis as the cause of important symptoms is relatively easy, it may be confused with pain caused by duodenal ulcer, disease of the right kidney, pancreatitis or cancer of the pancreas. A still further point of confusion is that gall stones may be found in association with any of these conditions. The pains of lead colic, tabetic crisis, angina abdominalis and other rare conditions such as porphyria and polyarteritis nodosa can be differentiated only with great difficulty from those due to biliary colic. A very important point in differential diagnosis has already been discussed under *Diseases of the Liver*. Acute infectious or toxic hepatitis and, less commonly, cirrhosis of the liver may be characterized by episodes of severe right upper quadrant pain and jaundice. A careful history and physical examination may reveal the presence of intrahepatic disease and provide an adequate explanation for the attack of abdominal pain. Confirmatory evidence may be obtained by proper liver function tests. Under such circumstances an exact diagnosis must be obtained, inasmuch as unnecessary and ill advised surgery in the presence of intrahepatic disease is extremely dangerous and may produce fatal results.

Possibly the most difficult diagnostic problem that exists in relation to the possible existence of gall stones is that of painless jaundice. On occasion progressive jaundice due to stones in the common duct may occur without any accompanying history of pain or discomfort. Under these circumstances gradual enlargement of the liver may occur with accompanying clay-colored stools and deeply bile stained urine. No additional symptoms may be present except for pruritis, but anorexia, loss of weight, nausea and vomiting may accompany the condition. In the complete absence of pain or discomfort, such a situation involves consideration of three important conditions: (1) stone in the common duct, (2) cancer of the head of the pancreas, of the ampulla of Vater or of the common duct, and (3) infectious hepatitis. Absolute certainty as to the diagnosis is not always possible, but certain important diagnostic features require careful attention. A so-called silent stone may underlie the presence of jaundice, but it is rare indeed that a carefully taken history will not reveal minor degrees of indigestion of months or years duration, even if there have been no episodes of colicky pain. The establishment of such a history points strongly to the presence of gall stones rather than to malignancy or intrahepatic infection, which are usually accompanied by symptoms of recent date. Physical examination will reveal intense jaundice in all three conditions. In infectious hepatitis the color of the jaundice is predominantly yellow to orange. In prolonged jaundice due to extra hepatic obstruction, the discoloration tends to be brownish or greenish. Hepatic enlargement may be the same in all three conditions, but in infectious hepatitis generalized liver tenderness is more apt to be present than in the presence of obstruction due to stone or neoplasm. The finding of a nodular liver immediately suggests the possibility of new growth. If it is possible to demonstrate enlargement of the spleen, important evidence has been obtained that is highly suggestive of intrahepatic disease rather than of extrahepatic block. A similar connotation may be given to the appearance

of spider angiomata. A palpable mass separate from the probable location of the gallbladder implies the probability of malignant disease. Of greater importance is the finding of a rounded rather elastic mass lying just below the hepatic border in the *midclavicular line, moving with respiration.* If this mass represents a distended gallbladder, the chances are almost certain that the cause of obstruction is extrahepatic and is due to a carcinomatous block of the common duct near or at the sphincter of Oddi. This is the basis for Courvoisier's law and is based upon the fact that obstruction to the flow of bile sufficient to produce intense jaundice is *capable of distending a normal gallbladder* to the point where it can be palpated. Exceptions to this rule are rare but do occur with the result that the finding of a palpable gallbladder in the presence of deep jaundice may indicate the remote possibility of an obstructing stone in the common duct and may justify exploratory surgery.

Laboratory tests that are helpful in the *evaluation of the problem of painless jaundice* may be considered as follows. In progressive obstruction to the outlet of the common duct by invading neoplasm, bile is usually completely absent from the duodenal contents and the stools and urinary urobilinogen is absent or present only in minimal quantities. In the partial obstruction accompanying stone in the common *duct or intrahepatic disease bile pigments* are demonstrable in the intestinal contents and urobilinogen in the urine is normal or even increased. Intrahepatic disease may be suggested by positive results in cephalin flocculation tests. Moderate elevation in the serum of alkaline phosphatase and cholesterol are typical of partial block due either to stone or to intrahepatic disease. The complete obstruction to the flow of bile caused by neoplasm is typically responsible for high values of alkaline phosphatase and cholesterol in the serum. The finding of occult blood in the stools is not diagnostic but, if persistent and *appreciable in quantity*, points toward a diagnosis of malignancy, particularly if hypoprothrombinemia is not marked. Radiological examination occasionally shows a calculus in the region of the common duct. A barium meal may give evidence of definite deformity of the outline of the first and second portions of the duodenum or of distortion of the mucosal pattern. Such a finding is highly suggestive of pancreatic or ampullary malignancy. A sudden decrease in the intensity of jaundice *may be associated with malignant disease of* the ampulla or with common-duct stone. It is more characteristic of the former and is usually associated with evidences of active bleeding from the upper gastrointestinal tract. This is due to the fact that the invading neoplasm has ulcerated in the region of the sphincter of Oddi. In spite of all of these considerations, a satisfactory explanation for *painless jaundice may be impossible, even* after exhaustive studies. In this event, it is usually wise to prepare the patient for exploratory laparotomy in order to establish a diagnosis and carry out proper treatment before the condition of the patient makes it impossible to do so.

*Treatment.*—The treatment of cholelithiasis should be limited to adequate and *well performed surgical maneuvers.* Any individual in otherwise good health in whom the presence of biliary calculi has been demonstrated should have elective cholecystectomy, with or without exploration of the common duct depending upon the actual condition found at operation. Medical treatment of gall stones has no place in proper therapy. Although it is undoubtedly *true that gall stones may remain* asymptomatic for years and may never result in serious complications, the fact remains that the danger of surgery as it is performed today by skilled operators is definitely less than the risks inherent in a policy of *watchful waiting.* In a small percentage of cases it may be proper to avoid surgery because of the presence of other serious disease. This is particularly true if serious renal or pulmonary disease exists. Heart disease in the absence of heart failure is not a contraindication to surgery. Indeed, many patients with coronary heart disease and angina pectoris also have gall stones which cause occasional attacks of biliary colic. In most instances surgical removal of the gall stones is advisable and frequently results in amelioration of the cardiac symptoms. In obviously *poor risk patients in whom repeated attacks*

of biliary colic have occurred cholecystostomy with removal of the stones may be the procedure of choice When gall stones exist in the presence of diabetes there is little doubt that cholecystectomy is indicated and the procedure may be expected to have a beneficial effect on the progress of the diabetes In uncomplicated cases the actual risk of cholecystectomy, with or without exploration of the common duct is between 2 and 4 per cent Obviously the presence of jaundice and cholangitis increases operative mortality but surgical intervention is important and necessary to prevent further complications

The surgical treatment of the acute gallbladder with biliary colic due to stones may be open to some controversy Most surgeons prefer to operate immediately during the attack if an early diagnosis is made If diagnosis is deferred however, and symptoms of acute or subacute cholecystitis have been present for some days then postponement of operation is advisable until the acute inflammatory process has subsided In this event an operation of election should be planned Exploration of the common duct in the absence of jaundice will depend upon the practice and skill of the individual surgeon In the presence of only one large stone in the gallbladder or in the absence of numerous small stones common-duct exploration may properly be avoided provided manual exploration of the duct does not reveal dilatation or suspicious areas suggesting the presence of intraductal stones If numerous small stones are present particularly if jaundice and/or fever have been present during attacks common-duct exploration should be carried out In cases in which a stone is impacted in the vicinity of the ampulla of Vater a transduodenal approach may be necessary to dislodge the calculus In cases in which jaundice has been present for some time the hemorrhagic tendency due to hypoprothrombinemia must be treated by the adequate administration of parenterally administered vitamin K If the obstruction has not produced any serious hepatic insufficiency normal prothrombin values will be obtained If this is impossible then the use of freshly drawn blood immediately preceding and during the operation may cover this particular lack inasmuch as it provides both prothrombin in normal amounts and accelerator globulin

*Complications of surgery* should be mentioned In spite of careful exploration of the common duct it is occasionally impossible to locate small calculi which may be left behind or which may actually appear from higher levels in the ductal system Under these circumstances there is usually a continuation of attacks of biliary colic with or without jaundice and subsequent re-exploration may be necessary Under these circumstances evidence confirmatory of the existence of biliary calculi or gravel may be obtained by studies of material obtained by duodenal drainage During the operation in some institutions the precaution of making a cholangiogram is taken in order to demonstrate hitherto unfound or unsuspected stones which may then be localized and removed When postoperative drainage of the common duct is considered necessary a cholangiogram should be made before the drainage tube is removed

A second complication of gallbaldder surgery is that of trauma to the common duct This is usually the result of carelessness but it occasionally occurs in spite of all possible precautions When the common duct is traumatized jaundice usually occurs a short time after operation It may be accompanied by fever and pain simulating biliary colic or it may result in the appearance of a biliary fistula usually draining through the operative incision Such an occurrence is extremely unfortunate and almost always necessitates further operation which is always difficult and of unpredictable value Reconstruction of a common duct that has already been damaged by trauma or by stenosis secondary to the inflammatory process surrounding impacted gall stones requires the utmost surgical skill If unsuccessful it invariably leads to biliary cirrhosis

CHOLECYSTITIS —Cholecystitis or inflammation of the gallbladder may be acute or chronic and is usually associated with the presence of biliary calculi It may occur in the absence of gall stones as a result of bacterial invasion The colon bacillus, the typhoid bacillus the pneumococcus the staphylococcus and the streptococcus have

of spider angiomata. A palpable mass separate from the probable location of the gallbladder implies the probability of malignant disease. Of greater importance is the finding of a rounded, rather elastic mass lying just below the hepatic border in the midclavicular line, moving with respiration. If this mass represents a distended gallbladder, the chances are almost certain that the cause of obstruction is extrahepatic and is due to a carcinomatous block of the common duct near or at the sphincter of Oddi. This is the basis for Courvoisier's law and is based upon the fact that obstruction to the flow of bile sufficient to produce intense jaundice is capable of distending a normal gallbladder to the point where it can be palpated. Exceptions to this rule are rare but do occur with the result that the finding of a palpable gallbladder in the presence of deep jaundice may indicate the remote possibility of an obstructing stone in the common duct and may justify exploratory surgery.

Laboratory tests that are helpful in the evaluation of the problem of painless jaundice may be considered as follows. In progressive obstruction to the outlet of the common duct by invading neoplasm, bile is usually completely absent from the duodenal contents and the stools and urinary urobilinogen is absent or present only in minimal quantities. In the partial obstruction accompanying stone in the common duct or intrahepatic disease, bile pigments are demonstrable in the intestinal contents and urobilinogen in the urine is normal or even increased. Intrahepatic disease may be suggested by positive results in cephalin-flocculation tests. Moderate elevation in the serum of alkaline phosphatase and cholesterol are typical of partial block due either to stone or to intrahepatic disease. The complete obstruction to the flow of bile caused by neoplasm is typically responsible for high values of alkaline phosphatase and cholesterol in the serum. The finding of occult blood in the stools is not diagnostic but, if persistent and appreciable in quantity, points toward a diagnosis of malignancy, particularly if hypoprothrombinemia is not marked. Radiological examination occasionally shows a calculus in the region of the common duct. A barium meal may give evidence of definite deformity of the outline of the first and second portions of the duodenum or of distortion of the mucosal pattern. Such a finding is highly suggestive of pancreatic or ampullary malignancy. A sudden decrease in the intensity of jaundice may be associated with malignant disease of the ampulla or with common-duct stone. It is more characteristic of the former and is usually associated with evidences of active bleeding from the upper gastrointestinal tract. This is due to the fact that the invading neoplasm has ulcerated in the region of the sphincter of Oddi. In spite of all of these considerations a satisfactory explanation for painless jaundice may be impossible, even after exhaustive studies. In this event, it is usually wise to prepare the patient for exploratory laparotomy in order to establish a diagnosis and carry out proper treatment before the condition of the patient makes it impossible to do so.

*Treatment.*—The treatment of cholelithiasis should be limited to adequate and well performed surgical maneuvers. Any individual in otherwise good health in whom the presence of biliary calculi has been demonstrated should have elective cholecystectomy with or without exploration of the common duct depending upon the actual condition found at operation. Medical treatment of gall stones has no place in proper therapy. Although it is undoubtedly true that gall stones may remain asymptomatic for years and may never result in serious complications, the fact remains that the danger of surgery as it is performed today by skilled operators is definitely less than the risks inherent in a policy of watchful waiting. In a small percentage of cases it may be proper to avoid surgery because of the presence of other serious disease. This is particularly true if serious renal or pulmonary disease exists. Heart disease in the absence of heart failure is not a contraindication to surgery. Indeed many patients with coronary heart disease and angina pectoris also have gall stones which cause occasional attacks of biliary colic. In most instances surgical removal of the gall stones is advisable and frequently results in amelioration of the cardiac symptoms. In obviously poor risk patients in whom repeated attacks

*Diagnosis.*—In cases in which the patient is examined during a mild attack the demonstration of localized tenderness over the gallbladder area may be sufficient to warrant a definite diagnosis. If fever and leukocytosis are present further important evidence has been obtained. Under these circumstances careful roentgenological studies of the entire gastrointestinal tract are indicated following cholecystography. In the absence of demonstrable abnormalities in the gastrointestinal tract the finding of a nonfunctioning gallbladder will be sufficient to warrant elective surgical intervention. It must be admitted, however, that chronic gallbladder disease falls into somewhat the same category as that of chronic appendicitis and failure to demonstrate clearly abnormal gallbladder function should leave the diagnosis of cholecystitis open to serious doubt.

*Treatment.*—Where the evidence of impaired gallbladder function is clear and there is no proof of other organic disease to be found cholecystectomy is indicated. However it is important to emphasize the fact that removal of a chronically inflamed gallbladder may result in no amelioration of symptoms if gall stones are not present. Indeed a very high percentage of cholecystectomies performed for chronic gallbladder disease do little but leave the patient with an abdominal scar and persisting symptoms. Specific medical measures directed toward improving gallbladder function including the therapeutic use of duodenal drainage are of very dubious value.

BILIARY DYSKINESIA.—This term implies the occurrence of biliary colic due solely to spastic contraction of the sphincter of Oddi in the absence of gall stones or of disease of the gallbladder. Such a cause of attacks of right upper-quadrant colicky pain undoubtedly exists but the exact mechanism is not clear. It may be associated with spasm of the duodenum in the vicinity of the ampulla and in specific instances it may be produced in otherwise normal individuals by the administration of morphine or by balloon distention of the duodenum. Whether spasm of the sphincter of Oddi occurs alone is not absolutely known. Consideration of the existence of such a disturbance is of particular importance in individuals who suffer from recurrent attacks of biliary colic after adequate surgical removal of a diseased gallbladder and biliary calculi in the gallbladder or bile ducts. Under these circumstances it is extremely important to avoid secondary surgery and the diagnosis of biliary dyskinesia may be accepted as an explanation for the patient's symptoms if other evidence of cholelithiasis or inflammation of the bile ducts is lacking.

The validity of such a diagnosis may be strengthened by the performance of certain maneuvers. Attacks of pain may be produced by the use of small doses of morphine. Painful episodes may follow the ingestion of such a substance as egg yolk which theoretically produces spasm of the sphincter of Oddi. The use of nitroglycerine may give prompt relief to spontaneously occurring attacks of pain or to those following the ingestion of fatty substances. If the tip of a duodenal tube is placed in position in the duodenum opposite the sphincter of Oddi pain produced by the ingestion of egg yolk or some similar substance may be promptly relieved by the instillation of a solution of magnesium sulphate. With relief of pain a flow of bile should promptly appear. The diagnosis of biliary dyskinesia should never be accepted until thorough studies have conclusively ruled out the possibility of cholelithiasis or disease of the biliary passages or neighboring structures.

CARCINOMA OF THE GALLBLADDER AND BILE DUCTS.—In nearly every instance tumors of the gallbladder and ducts are carcinomatous in nature. In the gallbladder the histological classification may be that of carcinoma simplex, adenocarcinoma or squamous cell carcinoma. In the ducts the scirrhous type of cancer is most frequently encountered although soft extremely friable polypoid growths may occur within the common duct and may simulate gall stones. Although carcinoma of the gallbladder and bile ducts may occur without obvious cause it is in most instances associated with the presence of gall stones and a chronic inflammatory process of long standing. This point is of the utmost importance inasmuch as it emphasizes the wisdom of proper elective surgical procedures directed toward the removal of gall stones and chronically dis-

been the organisms most often found. Infection by Brucella organisms may be the responsible factor.

*Acute gallbladder infection* may occur in the course of the diseases caused by any of these organisms, or it may be encountered without any specific associated disease.

*Morbid Anatomy.*—The gallbladder is usually distended, and the walls tense. Inflammatory adhesions may be formed with the duodenum, the colon, or the omentum. The mucous membrane is swollen by a catarrhal condition, and, as the process continues, areas of necrosis develop and the villi may become hypertrophied, giving the gallbladder a strawberry appearance. A diffuse phlegmonous process may result, and perforation may occur.

*Symptoms and Signs.*—Severe paroxysmal pain, as a rule, is the first indication of the condition. It is most commonly experienced in the right upper quadrant. It may be epigastric in location or in the region of the appendix. Nausea, vomiting and an elevation of pulse and temperature are present usually, with abdominal distention, muscle spasm, and tenderness over the gallbladder area. The gallbladder may be palpable. Intestinal ileus may occur, with marked distention.

*Diagnosis.*—The diagnosis is usually readily made, but certain points of confusion require comment. During the course of intercurrent infection, such as typhoid fever or pneumonia, the appearance of right upper-quadrant pain and tenderness is highly suggestive of a complicating acute cholecystitis. When no other infectious disease is present, acute cholecystitis may simulate acute appendicitis, acute intestinal obstruction or subacute pancreatitis. The presence of fever and leukocytosis will be common to all of these conditions. Abdominal films will be useful primarily in ruling out acute intestinal obstruction. As a rule, the acuteness of the condition precludes immediate cholecystography or gastrointestinal studies, and the diagnosis must eventually rest upon the ultimate localization of tenderness and muscle spasm in the right upper-quadrant along with other evidences of severe acute infection.

*Treatment.*—In the milder cases, the inflammatory process subsides spontaneously with conservative measures. Recovery may be accelerated by the use of streptomycin, penicillin or similar antibiotic agents. In the severer forms, in which there is definite suppuration or a phlegmonous process in the gallbladder, subsidence of the attack may not occur, and, if improvement is not noted in a relatively short time, surgical intervention is indicated, with cholecystectomy. Occasionally, empyema and perforation of the gallbladder may occur, in which event surgical drainage alone may be the only proper immediate maneuver. In this case elective cholecystectomy should be planned after the acute process has subsided. In the milder cases, after evidence of inflammation has disappeared, cholecystography should be performed, and, if interference with gallbladder function can be demonstrated, elective cholecystectomy is indicated.

*Chronic Cholecystitis.*—Chronic cholecystitis may occur in the absence of gall stones and give rise to numerous episodes of mild right upper-quadrant discomfort and tenderness, along with vague symptoms of indigestion and dyspepsia. It may be present in the carrier state of typhoid fever and may be the result of a low grade, chronic inflammatory process due to enteric organisms or those of the Brucella group. The inflammatory process results in a gradual thickening and fibrosis of the walls of the gallbladder, with loss of the normal mucosal villi and a progressive diminution of contractile and concentrating activity. The gross appearance of the mucosa at times justifies the term "strawberry gallbladder."

The *symptoms* of chronic noncalculous cholecystitis may occur in periodic episodes but more commonly are so vague as to make accurate diagnosis difficult. More often than not, digestive symptoms primarily referred to the epigastrium or right upper quadrant and commonly attributed to chronic cholecystitis are found, on careful scrutiny, to be due to irregular eating habits, to faulty regulation of the bowels, to the excessive use of alcohol, tobacco, tea or coffee, or to fatigue and emotional disturbances.

*Diagnosis* —In cases in which the patient is examined during a mild attack the demonstration of localized tenderness over the gallbladder area may be sufficient to warrant a definite diagnosis If fever and leukocytosis are present further important evidence has been obtained Under these circumstances careful roentgenological studies of the entire gastrointestinal tract are indicated following cholecystography In the absence of demonstrable abnormalities in the gastrointestinal tract the finding of a nonfunctioning gallbladder will be sufficient to warrant elective surgical intervention It must be admitted however that chronic gallbladder disease falls into somewhat the same category as that of chronic appendicitis and failure to demonstrate clearly abnormal gallbladder function should leave the diagnosis of cholecystitis open to serious doubt

*Treatment* —Where the evidence of impaired gallbladder function is clear and there is no proof of other organic disease to be found cholecystectomy is indicated However it is important to emphasize the fact that removal of a chronically inflamed gallbladder may result in no amelioration of symptoms if gall stones are not present Indeed a very high percentage of cholecystectomies performed for chronic gallbladder disease do little but leave the patient with an abdominal scar and persisting symptoms Specific medical measures directed toward improving gallbladder function including the therapeutic use of duodenal drainage are of very dubious value

Biliary Dyskinesia —This term implies the occurrence of biliary colic due solely to spastic contraction of the sphincter of Oddi in the absence of gall stones or of disease of the gallbladder Such a cause of attacks of right upper-quadrant colicky pain undoubtedly exists but the exact mechanism is not clear It may be associated with spasm of the duodenum in the vicinity of the ampulla and in specific instances it may be produced in otherwise normal individuals by the administration of morphine or by balloon distention of the duodenum Whether spasm of the sphincter of Oddi occurs alone is not absolutely known Consideration of the existence of such a disturbance is of particular importance in individuals who suffer from recurrent attacks of biliary colic after adequate surgical removal of a diseased gallbladder and biliary calculi in the gallbladder or bile ducts Under these circumstances it is extremely important to avoid secondary surgery and the diagnosis of biliary dyskinesia may be accepted as an explanation for the patient s symptoms if other evidence of cholelithiasis or inflammation of the bile ducts is lacking

The validity of such a diagnosis may be strengthened by the performance of certain maneuvers Attacks of pain may be produced by the use of small doses of morphine Painful episodes may follow the ingestion of such a substance as egg yolk which theoretically produces spasm of the sphincter of Oddi The use of nitroglycerine may give prompt relief to spontaneously occurring attacks of pain or to those following the ingestion of fatty substances If the tip of a duodenal tube is placed in position in the duodenum opposite the sphincter of Oddi pain produced by the ingestion of egg yolk or some similar substance may be promptly relieved by the instillation of a solution of magnesium sulphate With relief of pain a flow of bile should promptly appear The diagnosis of biliary dyskinesia should never be accepted until thorough studies have conclusively ruled out the possibility of cholelithiasis or disease of the biliary passages or neighboring structures

Carcinoma of the Gallbladder and Bile Ducts —In nearly every instance tumors of the gallbladder and ducts are carcinomatous in nature In the gallbladder the histological classification may be that of carcinoma simplex adenocarcinoma or squamous cell carcinoma In the ducts the scirrhous type of cancer is most frequently encountered although soft extremely friable polypoid growths may occur within the common duct and may simulate gall stones Although carcinoma of the gallbladder and bile ducts may occur without obvious cause it is in most instances associated with the presence of gall stones and a chronic inflammatory process of long standing This point is of the utmost importance inasmuch as it emphasizes the wisdom of proper elective surgical procedures directed toward the removal of gall stones and chronically dis

cased gallbladders, as a safeguard against the future development of malignant lesions.

*Symptoms and Signs.*—The symptoms of malignant disease of the gallbladder or bile ducts will depend upon two factors: (1) the associated presence of biliary calculi and (2) the actual location of the tumor. Carcinoma of the fundus of the gallbladder eventually causes the appearance of dull, constant pain in the right-upper quadrant, with anorexia, loss of weight and weakness. Physical examination will frequently reveal a tender nodular or globular mass in the region of the gallbladder. Jaundice is a late manifestation. In cases in which the tumor is located in the ampulla of the cystic duct or within the lumen of the hepatic, cystic or common ducts, jaundice appears early and, in the absence of biliary calculi, may be unassociated with colicky pain. Where there is malignant involvement of the bile ducts, obstruction to the flow of bile is nearly always present and is usually accompanied by fever and frequently by chills. Metastasis to the liver is common and may be evident because of hepatic enlargement with nodularity. Ascites occurs in the presence of peritoneal implants. If biliary obstruction is marked, all the clinical and laboratory findings commonly observed in this condition may be present. A greenish tint to the discoloration of the skin is fairly characteristic, due to the formation of biliverdin in the bile ducts as a result of prolonged bile stasis.

*Diagnosis.*—The possibility of carcinomatous involvement of the gallbladder or bile ducts should be suggested by the appearance of the clinical features noted above. The fact that there may be a history of repeated attacks of biliary colic implies the existence of biliary calculi; the progressive nature of the advancing disease in most instances should also suggest the probability of additional malignant involvement. In cases in which the diagnosis is in doubt, three procedures may provide the necessary information. Obviously, exploratory laparotomy offers the surest means of identifying the underlying process. In many cases such a maneuver is undesirable because of the general condition of the patient, and diagnostic information may be obtained either by peritoneoscopy or by aspiration biopsy of the liver. Failure to obtain positive evidence of carcinomatous disease by either of these measures does not exclude the diagnosis of cancer. On infrequent occasions, early carcinoma of the gallbladder or of the bile ducts may be found at the time of surgical intervention directed toward the relief of symptoms secondary to demonstrable cholelithiasis or cholecystitis. Under these circumstances, very radical surgery may properly be performed and is occasionally attended with striking success.

## DISEASES OF THE PANCREAS

General Considerations.—The normal functions of the pancreas depend upon the presence of an internal secretion produced by the islands of Langerhans and an external secretion produced by the acinar tissue. The internal secretion, insulin, plays an essential role in the normal control of carbohydrate metabolism. In conditions in which inflammatory disease has destroyed a sufficient number of islet cells, diabetes mellitus may result. A total pancreatectomy, however, is usually associated with the development of a less intense form of diabetes, as judged by insulin requirements, than that encountered in patients with the spontaneously occurring disease. The external secretion contains several digestive ferments and is collected by a branching system of ducts, ducts which eventually lead into the main pancreatic duct, the duct of Wirsung. This discharges in company with the common bile duct, into the ampulla of Vater. In a certain proportion of cases, the pancreatic and the common bile duct open into the intestine by separate orifices. An accessory pancreatic duct, the duct of Santorini, which opens into the duodenum a little above the duct of Wirsung, is usually present. It also sends a branch to the main duct. The pH of the pancreatic juice is between 7.10 and 8.20. The principal ferments in the pancreatic juice are trypsinogen, pancreatic amylase (amylopsin) and pancreatic lipase (steapsin). Trypsinogen is activated by enterokinase, an enzyme derived from intestinal secretion, and carries the digestion of protein beyond the peptone stage. Unlike pepsin, it is active in an alka-

line medium Pancreatic amylase hydrolyzes starch in much the same manner as salivary amylase but is a much more powerful agent Part of the amylase is believed to be reabsorbed from the intestine In the presence of obstruction to the flow of pancreatic juice it appears in increased quantities in the circulating blood Pancreatic lipase splits the fat molecule into its constituents glycerine and fatty acid The latter combines with alkali to form soaps, which in turn act as an emulsifying agent The secretion of pancreatic juice is under both hormonal and nervous control The latter is mediated over the vagus nerves and produces a secretion that is low in volume but particularly rich in ferments This type of secretion is blocked by the administration of atropine The hormonal control of pancreatic secretion is affected by the action of a substance called secretin derived from the duodenal secretion and produced under the stimulation of acid chyme coming into contact with the duodenal mucosa The action of secretin is not reduced by the administration of atropine The volume of pancreatic external secretion is much greater after stimulation by secretin than after vagal stimulation Marked reduction in the amount of external pancreatic secretion due to pancreatic disease or to the exclusion of pancreatic secretion from the digestive tract, results in diarrhea or the passage of bulky pale stools containing varying amounts of undigested fat protein and starch Even total extirpation of the pancreas does not of necessity produce totally inadequate digestion of foodstuffs inasmuch as the succus entericus may provide sufficient enzyme activity to permit a reasonable degree of alimentation Diseases of the pancreas therefore may result in symptoms referable to hypoinsulinism or to those secondary to inadequate enzymatic digestion of food materials in the upper intestinal tract or to both factors

Pancreatic disease may be due to acute or chronic inflammatory processes to new growths or to cyst formation

PANCREATITIS — *Acute pancreatitis* is due to an inflammatory process produced by a variety of causes It may be the result of obstruction to the flow of external secretion with consequent escape of pancreatic enzymes into the acinar tissue It may be caused by bacterial invasion of the gland Occasionally it occurs as the result of the rupture of a large vessel with sudden hemorrhage into the organ In certain cases hemorrhagic pancreatitis is due to obstruction of the outlet of the ampulla of Vater and the consequent passage of bile into the pancreatic duct system Such an occurrence may be secondary to the presence of a gall stone obstructing the ampulla or to swelling of the sphincter of Oddi or of the adjacent duodenal mucosa (Archibald) According to Dragstedt and his associates only about 60 per cent of the cases of hemorrhagic pancreatitis arise in subjects with chronic biliary tract disease and in only about 10 per cent of these is the ampulla obstructed by a gall stone When a reflux of bile into the pancreas occurs the subsequent rupture of the duct wall and the escape of the pancreatic juice into the interstitial tissue of the pancreas is thought to be the essential factor in the production of the hemorrhagic lesion According to Rich and Duff obstruction to the flow of pancreatic juice may be due to metaplasia of the epithelial lining of a branch of the pancreatic duct within the gland with resultant rupture of a dilated ductule or acinus This is more likely to occur when the secretion pressure of pancreatic juice is high—*i e* after a large meal or the ingestion of alcohol As a result of some form of obstruction to the flow of pancreatic juice, or as a result of actual infection of the pancreatic tissue hemorrhages occur into the glandular substance with necrosis of cells This is accompanied by the escape of lipase *from the disorganized gland with resultant* fat necrosis in the mesentery omentum and peritoneum as well as in the pancreas itself Where hemorrhagic necrosis is extreme a sanguinous fluid is usually found in the peritoneal cavity

*Symptoms and Signs* — The severity of symptoms varies with the degree of involvement of the acinar tissue The onset is usually sudden with excruciating epigastric or upper abdominal pain This pain may radiate to the back usually to the left of the spine Vomiting is a prominent symptom particularly if the attack occurs after a heavy

eased gallbladders, is a safeguard against the future development of malignant lesions.

*Symptoms and Signs.*—The symptoms of malignant disease of the gallbladder or bile ducts will depend upon two factors: (1) the associated presence of biliary calculi and (2) the actual location of the tumor. Carcinoma of the fundus of the gallbladder eventually causes the appearance of dull constant pain in the right upper-quadrant with anorexia, loss of weight and weakness. Physical examination will frequently reveal a tender nodular or globular mass in the region of the gallbladder. Jaundice is a late manifestation. In cases in which the tumor is located in the ampulla of the cystic duct or within the lumen of the hepatic, cystic or common ducts, jaundice appears early and, in the absence of biliary calculi, may be unassociated with colicky pain. Where there is malignant involvement of the bile ducts, obstruction to the flow of bile is nearly always present and is usually accompanied by fever and frequently by chills. Metastasis to the liver is common and may be evident because of hepatic enlargement with nodularity. Ascites occurs in the presence of peritoneal implants. If biliary obstruction is marked, all the clinical and laboratory findings commonly observed in this condition may be present. A greenish tint to the discoloration of the skin is fairly characteristic, due to the formation of biliverdin in the bile ducts as a result of prolonged bile stasis.

*Diagnosis.*—The possibility of carcinomatous involvement of the gallbladder or bile ducts should be suggested by the appearance of the clinical features noted above. The fact that there may be a history of repeated attacks of biliary colic implies the existence of biliary calculi; the progressive nature of the advancing disease, in most instances, should also suggest the probability of additional malignant involvement. In cases in which the diagnosis is in doubt, three procedures may provide the necessary information. Obviously exploratory laparotomy offers the surest means of identifying the underlying process. In many cases such a maneuver is undesirable because of the general condition of the patient and diagnostic information may be obtained either by peritoneoscopy or by aspiration biopsy of the liver. Failure to obtain positive evidence of carcinomatous disease by either of these measures does not exclude the diagnosis of cancer. On infrequent occasions, early carcinoma of the gallbladder or of the bile ducts may be found at the time of surgical intervention directed toward the relief of symptoms secondary to demonstrable cholelithiasis or cholecystitis. Under these circumstances very radical surgery may properly be performed and is occasionally attended with striking success.

## DISEASES OF THE PANCREAS

GENERAL CONSIDERATIONS.—The normal functions of the pancreas depend upon the presence of an internal secretion produced by the islands of Langerhans and an external secretion produced by the acinar tissue. The internal secretion, insulin, plays an essential role in the normal control of carbohydrate metabolism. In conditions in which inflammatory disease has destroyed a sufficient number of islet cells, diabetes mellitus may result. A total pancreatectomy, however, is usually associated with the development of a less intense form of diabetes, as judged by insulin requirements, than that encountered in patients with the spontaneously occurring disease. The external secretion contains several digestive ferments and is collected by a branching system of ducts, ducts which eventually lead into the main pancreatic duct, the duct of Wirsung. This discharges, in company with the common bile duct, into the ampulla of Vater. In a certain proportion of cases the pancreatic and the common bile duct open into the intestine by separate orifices. An accessory pancreatic duct, the duct of Santorini, which opens into the duodenum a little above the duct of Wirsung, is usually present. It also sends a branch to the main duct. The pH of the pancreatic juice is between 7.10 and 8.20. The principal ferments in the pancreatic juice are trypsinogen, pancreatic amylase (amylopsin) and pancreatic lipase (steapsin). Trypsinogen is activated by enterokinase, an enzyme derived from intestinal secretion, and carries the digestion of protein beyond the peptone stage. Unlike pepsin, it is active in an alka-

the inflammatory process may alter the external secretion to a degree sufficient to cause the formation of small calculi which may obstruct the small ducts or even become impacted in the duct of Wirsung with accompanying obstruction to the flow of pancreatic juice and as a result pain The degree of fibrosis and degeneration present in a given gland will determine the character of the symptoms

*Symptoms and Signs* —Where extensive degeneration and fibrosis have occurred the patient complains of alteration of bowel habits and a change in the character of the stools Frank diarrhea may occur but more often the condition is characterized by the frequent passage of bulky or frothy grayish or light yellow stools that glisten because of the high fat content They are usually extremely foul Weight loss may be a striking feature and a certain degree of malnutrition is invariably present Pain may be entirely lacking but when present is usually epigastric in location with radiation through to the back It is usually brought on by the ingsetion of food containing appreciable quantities of fats or proteins Alcohol in excess also initiates attacks of pain Jaundice is a variable feature and usually depends on whether the head of the pancreas is involved by a fibrosing process in close proximity to the ampulla of Vater The jaundice may be due however to the associated presence of biliary calculi Diabetes mellitus with glycosuria may be present but is by no means a constant accompaniment of the condition Physical examination reveals general malnutrition During episodes of pain tenderness over the area of the entire pancreas can usually be demonstrated

*Diagnosis* —A history of gradually increasing change in bowel activity with the passage of fatty stools and an accompanying loss of weight should suggest the possibility of chronic pancreatitis The occurrence of epigastric pain with radiation into the back occurring after the intake of food or alcohol is further important diagnostic evidence Laboratory measures are limited Where chronic pancreatitis is accompanied by severe attacks of pain one may expect to find an elevation of serum amylase It should be remembered however that progressive destruction of the gland may reduce the production of pancreatic amylase to a point where elevated values in the serum may not be possible In the absence of this specific test determinations of pancreatic enzyme activity either by microscopic examination of the stools or by study of the duodenal contents may give a clue to the underlying process In advanced cases the stools will invariably show excessive amounts of fat or fatty acid and the presence of numerous undigested muscle fibers provided the patient is taking appreciable quantities of fatty substances and red meat Analysis of the duodenal contents for enzyme determinations requires special laboratory techniques The flow of pancreatic juice may be stimulated by the administration of secretin or cholinergic drugs or by the ingestion of a fatty meal or a meal containing peptones An experienced technician may be able to demonstrate levels of enzyme activity far below those encountered in normal individuals A film of the upper abdomen is frequently of great help in demonstrating disseminated calcification of the pancreas or in suggesting the presence of pancreatic calculi

*Treatment* —When pain is not a prominent feature essential treatment consists primarily in the use of potent pancreatic extracts These are now available and contain adequate amounts of potent proteolytic lipolytic and amylolytic enzymes which may be administered with the meals The use of these preparations is at times accompanied by improvement in intestinal absorption with modification of the stools and a reduction in the degree of intestinal flatulence The addition of an emulsifying agent such as Tween-80 may increase fat absorption It is rarely possible to correct completely the deficiency in pancreatic enzyme activity When diabetes is present it should be treated according to the general principles embodied in the therapy of this disease In cases in which pain is an important feature the therapeutic problem is a complicated one inasmuch as these patients tend to become addicted to the use of morphine or its derivatives or to the excessive use of alcohol which at times relieves abdominal discomfort

meal or the excessive intake of alcohol. Epigastric tenderness is almost invariably present, and, where extensive necrosis exists, the tenderness may extend well to the left of the midline, going over to the region over the tail of the pancreas. Left costovertebral angle tenderness may occur. In severe cases symptoms of shock are marked, with rapid pulse, low blood pressure and extreme pallor or cyanosis. Fever is almost invariably present except in the mildest cases. Jaundice may be present but is usually of only moderate intensity. The patient may die within a few hours of the onset of the disease, but usually the course of the disease covers a period of several days or weeks. In serious cases the progress of the disease may be marked by electrolyte loss and dehydration, the appearance of ascites and occasionally the signs of frank tetany.

*Diagnosis* usually is made on the basis of an acute fulminating attack and physical signs. The condition must be differentiated from perforation of a gastric or duodenal ulcer, acute cholecystitis, intestinal obstruction and acute peritonitis with rupture. Coronary thrombosis may simulate an acute hemorrhagic pancreatitis and occasionally the condition is confused with diaphragmatic pleurisy and pneumonia. In acute hemorrhagic pancreatitis muscle rigidity may be encountered, but it is much less marked than that associated with a perforated viscus. Abdominal tenderness is more in the midline or to the left of the midline than that commonly encountered in acute cholecystitis. An attack of coronary thrombosis may be associated with severe abdominal pain, but a careful history will usually elicit a previous story of angina pectoris or exertional dyspnea. Abdominal films to exclude the presence of gas under the diaphragm will be helpful in deciding against the diagnosis of a perforated ulcer. The white blood cell count in acute hemorrhagic pancreatitis usually reaches a very high level, but this in itself is not diagnostic. The most important single laboratory test is the determination of serum amylase. During the acute stage of the disease serum amylase values may be several times the normal value and in most instances such a findin is practically diagnostic of the condition. Amylase values may fall rapidly as the attack progresses. Therefore, several early determinations are important.

*Treatment.*—In recent years conservative therapy has been strongly advocated because of the high mortality rate attending earlier operative procedures and because of the fact that a very large number of patients with acute pancreatitis recover spontaneously. Initial measures should include the parenteral administration of adequate amounts of fluid and electrolytes. In the presence of shock whole-blood transfusions or the use of plasma when blood is not immediately available may be a life saving procedure. Oral feeding should be avoided at least in the early stages of the disease. Absolute bed rest and the use of sufficient quantities of morphine to relieve pain are essential. If the course of the disease suggests a suppurative process antibiotic therapy should be employed, and when tetany is present due to a striking lowering of the blood calcium the intravenous administration of calcium gluconate is an important measure. In the presence of shock surgery should be avoided, but with general improvement in the condition of the patient surgical intervention may be proper if there are evidences of spreading peritonitis or increasing icterus. Surgical maneuvers should be limited to cholecystostomy and simple drainage. A late complication of the disease may be that of abscess formation due to local suppuration. When this complication occurs surgical drainage is necessary. If gall stones are demonstrated after the attack has subsided proper elective surgical measures should be planned.

*Prognosis.*—The mortality rate for this condition ranges between 10 and 30 per cent. Recurrences of the condition may occur especially if biliary calculi are present in the common duct.

Chronic Pancreatitis.—Chronic pancreatitis is difficult to diagnose with any degree of consistency. The disease is usually the result of chronic or recurrent inflammation of the gland with consequent degeneration of pancreatic tissue and fibrosis. The degenerative process may be associated with extensive areas of calcification indicative of previous hemorrhage or necrosis. At times

the inflammatory process may alter the external secretion to a degree sufficient to cause the formation of small calculi which may obstruct the small ducts or even become impacted in the duct of Wirsung with accompanying obstruction to the flow of pancreatic juice and as a result pain The degree of fibrosis and degeneration present in a given gland will determine the character of the symptoms

*Symptoms and Signs* —Where extensive degeneration and fibrosis have occurred the patient complains of alteration of bowel habits and a change in the character of the stools Frank diarrhea may occur but more often the condition is characterized by the frequent passage of bulky or frothy, grayish or light yellow stools that glisten because of the high fat content They are usually extremely foul Weight loss may be a striking feature and a certain degree of malnutrition is invariably present Pain may be entirely lacking but when present is usually epigastric in location with radiation through to the back It is usually brought on by the ingestion of food containing appreciable quantities of fats or proteins Alcohol in excess also initiates attacks of pain Jaundice is a variable feature and usually depends on whether the head of the pancreas is involved by a fibrosing process in close proximity to the ampulla of Vater The jaundice may be due however to the associated presence of biliary calculi Diabetes mellitus with glycosuria may be present but is by no means a constant accompaniment of the condition Physical examination reveals general malnutrition During episodes of pain tenderness over the area of the entire pancreas can usually be demonstrated

*Diagnosis* —A history of gradually increasing change in bowel activity with the passage of fatty stools and an accompanying loss of weight should suggest the possibility of chronic pancreatitis The occurrence of epigastric pain with radiation into the back occurring after the intake of food or alcohol is further important diagnostic evidence Laboratory measures are limited Where chronic pancreatitis is accompanied by severe attacks of pain one may expect to find an elevation of serum amylase It should be remembered however that progressive destruction of the gland may reduce the production of pancreatic amylase to a point where elevated values in the serum may not be possible In the absence of this specific test determinations of pancreatic enzyme activity, either by microscopic examination of the stools or by study of the duodenal contents may give a clue to the underlying process In advanced cases the stools will invariably show excessive amounts of fat or fatty acid and the presence of numerous undigested muscle fibers provided the patient is taking appreciable quantities of fatty substances and red meat Analysis of the duodenal contents for enzyme determinations requires special laboratory techniques The flow of pancreatic juice may be stimulated by the administration of secretin or cholinergic drugs or by the ingestion of a fatty meal or a meal containing peptones An experienced technician may be able to demonstrate levels of enzyme activity far below those encountered in normal individuals A film of the upper abdomen is frequently of great help in demonstrating disseminated calcification of the pancreas or in suggesting the presence of pancreatic calculi

*Treatment* —When pain is not a prominent feature essential treatment consists primarily in the use of potent pancreatic extracts These are now available and contain adequate amounts of potent proteolytic lipolytic and amylolytic enzymes which may be administered with the meals The use of these preparations is at times accompanied by improvement in intestinal absorption with modification of the stools and a reduction in the degree of intestinal flatulence The addition of an emulsifying agent such as Tween 80 may increase fat absorption It is rarely possible to correct completely the deficiency in pancreatic enzyme activity When diabetes is present it should be treated according to the general principles embodied in the therapy of this disease In cases in which pain is an important feature the therapeutic problem is a complicated one inasmuch as these patients tend to become addicted to the use of morphine or its derivatives or to the excessive use of alcohol which at times relieves abdominal discomfort

When the problem of intractable pain is present, surgical intervention is frequently indicated. Two major surgical maneuvers require consideration. Total pancreatectomy may be performed. Such a radical procedure is justified only in extreme cases and should be avoided, if possible, because of the undesirable side effects. The resultant diabetes must be taken care of and the dietary and medicinal measures necessary to maintain nutrition are very complicated.

*Morbid Anatomy.*—The characteristic lesion is a widespread change in the mucus secreting glands of the entire body. The striking findings in the pancreas are but one manifestation. In the pancreas, initially, dilatation of the acini and the ducts is followed by atrophy of the acinar tissue. This tissue is replaced with connective tissue and ultimately, there is widespread fibrosis. Striking changes are characteristically found in the lungs and in the acini and the ducts of

FIG. 212.—Calcification of pancreas (head) with one large calculus in duct of Wirsung.

An entirely different maneuver which may give adequate symptomatic relief is that of splanchnicectomy. A left splanchnicectomy occasionally gives complete relief from pain but, in some instances, bilateral section of the sensory pathways may have to be performed.

CYSTIC FIBROSIS OF THE PANCREAS is a familial congenital disease characterized by steatorrhea due to insufficiency of the external secretion of the pancreas. It is associated with chronic bronchitis, bronchiolitis, recurrent bronchopneumonia and bronchiectasis. The disease is uncommon but may occur in more than one member of a family.

the salivary glands, and fatty infiltration of the liver is usually present.

*Clinical manifestations* are usually those of nutritional disturbances secondary to grossly deficient or absent pancreatic enzymes. Foul bulky stools appear early in infancy and in children afflicted with the condition who survive the first six months of life emaciation is extreme. About half the infants die of associated pulmonary infection secondary to widespread bronchiolar obstruction by thick tenacious mucus. The longest recorded survival is 14½ years.

*Diagnosis* of the condition is based upon recognition of symptoms secondary to pancreatic insufficiency in combination with

chronic pulmonary disease Examination of the stools reveals obvious steatorrhea and nitrogen loss Vitamin A absorption curves demonstrate poor absorption of the vitamin Roentgenological studies of the gastrointestinal tract are not diagnostic but show the changes characteristic of deficiency disease

*Treatment* consists in the administration of potent pancreatic extract in adequate *amounts plus a well balanced diet* The use of vitamin A preparations may be of extreme importance in growing children and, at times it may be necessary to combat hypo-

The *diagnosis* of islet-cell tumor is based on the occurrence of repeated episodes of typical spontaneous hypoglycemia These attacks must be differentiated from those occurring as a result of hepatic disease hypopituitarism adrenal-cortical insufficiency, and hypothyroidism as well as from those without demonstrable anatomical lesions classified as functional hypoglycemia

*Treatment* consists in surgical removal of the tumor or tumors and in most instances is eminently successful (*See* Chapter 15)

MALIGNANT TUMORS of the pancreas are practically always carcinomatous and arise

FIG 213 —Carcinoma of the head of the pancreas removed surgically An applicator is inserted in the common bile duct (Herbut s Surgical Pathology )

thrombinemia secondary to diminished absorption of fat soluble vitamin K Measures directed toward the prevention or care of pulmonary infection are obviously necessary

TUMORS OF THE PANCREAS —Both benign and malignant tumors of the pancreas are encountered The former are practically always benign adenomas of islet cells and symptoms are essentially due to hyperinsulinism with the production of hypoglycemic attacks Occasionally metastases may occur but they are unusual Islet tumors occur *most frequently in the body or tail of the* pancreas and are often multiple

from the acinar or duct epithelium Pancreatic cancer is extremely common and is *most frequently found in the head of the organ* It occurs very much more frequently in men than in women and is usually encountered in the later decades of life There may be an increased incidence of this condition in diabetic patients and it is not infrequently associated with the presence of gall stones

*Symptoms and Signs* —The symptoms and physical signs of cancer of the pancreas depend largely on the exact location of the lesion When cancer occurs in the tail or body of the organ there may be no symptoms until metastases occur In cancer of

the body of the pancreas pain is commonly encountered, due either to more or less accompanying obstruction of the main pancreatic duct or to involvement of the celiac plexus The pain is usually described as a deep steady boring discomfort It seems to originate in the epigastrium and typically radiates posteriorly to the back in the left lower thoracic region or in the interscapular area When severe it is relieved only by the hypodermic use of morphine or similar drugs Cancer of the head of the pancreas is typically accompanied by the gradual onset of gross evidence of increased amounts of fat A palpable mass may be present and in advanced cases, metastases to the liver may be evidenced by the finding of hepatic enlargement with nodularity

*Diagnosis* —Diagnosis of cancer of the tail or body of the pancreas must be made on purely clinical grounds Diagnosis of cancer of the head of the pancreas must be differentiated from cancer of the ampulla of Vater or common bile duct and from biliary obstruction due to stone in the common duct Many of the differential points have already

Fig 214 —Carcinoma of the head of the pancreas Note the displacement of the duodenal loop and the pressure on the greater curvature of the stomach (Portis Diseases of the Digestive System )

jaundice, which increases steadily until the patient is deeply pigmented Itching may be present and at times is intolerable Pain is a frequent accompaniment of the condition and is usually steady and boring in character The presence of gall stones is not uncommon and this fact may modify the picture because of episodes of colicky pain Loss of weight may be marked and both loss of appetite and actual distaste for food are commmon Increased frequency of bowel movements may occur, and the stools frequently show been discussed in detail under *painless jaundice* Direct evidence of carcinomatous involvement of the head of the pancreas may be obtained by the use of a barium meal with demonstrable deformity or alteration in the mucosal pattern of the first and second portions of the duodenum

*Treatment* —Treatment of cancer of the pancreas is limited to surgical procedures In spite of the brilliant operative results obtained by Whipple and others it is still true that a successful surgical cure of this

condition is extremely uncommon This is largely due to two factors first the diagnosis is usually not made until the disease is well advanced second metastases to regional lymph nodes the thoracic duct and adjacent blood vessels render adequate surgery almost impossible Total pancreatectomy is a formidable procedure but has been successfully accomplished in a number of instances It should be attempted only when the patient is in reasonably good physical condition and when the services of an unusually competent surgeon are available When such a radical procedure is not advisable palliative measures will be of help in the temporary elimination of jaundice and itching This may be accomplished by the external biliary drainage of the dilated common duct or by the performance of a cholecystgastrostomy or cholecyst-enterostomy Survival after any of these surgical procedures however is usually short

CYSTS OF THE PANCREAS —The most common cysts of the pancreas are classified as pseudocysts and are the result of trauma or inflammation of the organ They develop outside the body of the pancreas and do not contain pancreatic enzymes True cysts of the pancreas may result from obstruction to the main duct or its tributaries or may occur following a hemorrhagic or necrotizing process in the body of the gland Parasitic cysts are rare Proliferation cysts are usually associated with tumor formation Retention cysts and proliferation cysts usually contain active pancreatic enzymes

*Symptoms* —The symptoms obviously depend upon the location of individual cysts and the rapidity with which they develop Pseudocysts usually develop rapidly following severe trauma to the epigastrium or an acute attack of pancreatitis Epigastric swelling develops rapidly with a sensation of fullness and tension Pain may be present The development of other types of pancreatic cysts is more gradual and is usually not accompanied by pain unless there is hemorrhage into the cystic area If cystic involvement of the pancreas is associated with malignant disease the symptoms of loss of weight and malignant cachexia will be present

*Diagnosis* —The cystic mass may be readily palpable as a spheroid tumor that is not excessively hard It may increase in size till it is readily visible Roentgenological examination will usually provide information leading to a reasonably exact diagnosis Barium meal will show the tumor mass to be outside the stomach the duodenum or the upper small bowel At times a barium enema may be necessary to provide evidence that the tumor is external to the transverse colon Abdominal films will usually demonstrate a rounded or lobular radio-opaque mass Intravenous pyelograms may be necessary to rule out left renal tumor

*Treatment* —When symptoms are present or the cystic tumor is steadily increasing in size surgical intervention is necessary Excision of unilocular cysts may be possible but this is not always the case Marsupialization is frequently necessary When this is performed continued suction must be carried out until sclerosing solutions can be used to stop active secretion by the lining cells A persistent fistula can be transplanted successfully into the stomach or the adjacent small bowel

# Chapter 28

# Diseases of the Locomotor System

By STACY R. METTIER, M.D.

## THE JOINTS

### Arthritis

The amount of morbidity and invalidism produced by diseases of the locomotor system is appalling. It has been estimated that *320,000 persons are rendered unemployable annually* by the rheumatic diseases alone.

In recent years an increasing amount of interest has been shown in the subject of arthritis by physicians and investigators alike. In the Scandinavian countries hospitals have been set aside solely for the care of patients with diseases of the joints.

Some idea of the tremendous amount of interest shown in this subject may be gained from the fact that the material from the Eighth Rheumatism Review which appeared in *1940* was culled from *616* articles and *8* books. During World War II, the review was discontinued but it reappeared again in 1948 with information abstracted from 1995 articles.

The American Rheumatism Association adopted the following provisional classification at its June 1941 meeting:

1. Specific infectious arthritis (organism known)
   - (*a*) Gonorrheal arthritis
   - (*b*) Pneumococcal arthritis
   - (*c*) Tuberculous arthritis
   - (*d*) Brucellosis arthritis
2. Arthritis of rheumatic fever
3. Rheumatoid arthritis (synonyms: atrophic, proliferative and chronic nonspecific infectious arthritis, Still's disease, Marie-Strumpell spondylitis)
4. Osteo-arthritis (synonyms: degenerative joint disease, hypertrophic senescent arthritis)
5. Arthritis of immediate traumatic origin
6. Arthritis of gout
7. Arthritis of neuropathic origin (Charcot's joint)
8. Neoplasms of joints
9. Miscellaneous forms (arthritis associated with other diseases)

The term "rheumatism" has come down to us through the ages. It is a poor term but according to Snyder it still remains the best word to use in referring to that large group of diseases characterized by pain and stiffness in the ligaments, muscles and joints.

*Examination of the Patient.*—In attempting to make a diagnosis it is advisable to follow a well formed plan of study. A carefully taken medical history should include an inquiry into possible familial predisposition to disease of the joints or muscles, past history of rheumatic fever and exposure to or infection with gonococcus, tubercle bacillus, pneumococcus or other infectious agents that tend to be of a recurrent nature and are

may be the association of keratotic areas in the skin with polyarthritis This combination is being given consideration as a distinct entity and is described in the literature as 'keratosis blenorrhagica Ninety seven cases have been collated from the literature It is noted that the joint manifestations usually precede the appearance of the skin lesions The condition is unusual in that there is simultaneous involvement of several joints which in addition to the usual site may include the acromioclavicular joints

*Treatment of Gonorrheal Arthritis and Gonorrheal Rheumatism* —*See* Chapter 5

### Tuberculous Arthritis

Recent reviews indicate that tuberculous arthritis is of less frequent occurrence than formerly reported This decline is attributed to strict supervision over tuberculin tested milk cows, and to better eating and good hygienic habits on the part of the people

Tuberculous arthritis usually is monarticular in distribution In Dickson's report of 158 cases of tuberculous arthritis the frequency with which the joints were involved was as follows the spine in 62 cases hip in 41 knee in 25 ankle in 11 wrist in 10 sacro-iliac in 6 shoulder in 2 and elbow in 1 case The symptoms of tuberculous arthritis are generally characterized by the slow insidious development of pain and swelling There may be slight local warmth If a weight bearing joint is involved the patient may limp As the disease progresses pain and stiffness increase especially if the synovia is involved Affected children not infrequently utter night cries and may exhibit jerking of the lower extremities due to relaxation of the spastic muscles The disease at first may be extra articular and exist for years before rupturing into a joint cavity

*Tuberculosis of the Spine* (*Pott's Disease—Tuberculous Spondylitis*) is a local manifestation of a chronic tuberculous infection elsewhere in the body Trauma may be a predisposing factor in the development of a locus minoris resistentiæ The process begins most often in the cancellous portion of the anterior part of the body of the vertebra

One or more of the lower thoracic vertebræ may be damaged, and as the disease progresses bone is destroyed and finally the structure of the vertebra collapses Caseation of tissue leads to abscess formation Such an abscess may undermine the anterior common ligament and spread by extension to the adjacent vertebræ or extend along the anterior surface of the spine to form a psoas abscess

### Brucellosis

### (*Undulant Fever, Malta Fever*)

Acute polyarthritis may occur during the course of brucellosis In the acute phase of illness, arthralgia generalized body aches muscle pains and backache may be severe Joint manifestations usually are transitory and persistence of chronic joint disease seldom occurs Intermittent hydrarthrosis may develop but does not lead to suppurative arthritis

### Arthritis in Other Infectious Diseases

Of the numerous cases reported of arthritis as a complication of *lobar pneumonia* the incidence varies from as low as 0 1 to 6 5 per cent Since the introduction of chemotherapy it has almost disappeared The arthritis is usually monarticular and shows effusion in the joint cavity and swelling of the periarticular tissues Cultures should be made of fluid aspirated from the joint in order to be certain of the infectious agent

Articular swelling may appear during the course of *typhoid fever* It may be monarticular or polyarticular in distribution Usually the swelling is due to a serous effusion which may become septic Spondylitis (typhoid spine) may arise as a complication of typhoid fever

An arthrosis may be seen occasionally in subacute bacterial endocarditis The joints are usually painful slightly reddened and show only slight or a moderate degree of swelling The swelling is transitory

Arthritis is not an uncommon finding in *cerebrospinal meningitis* It may be monarticular or polyarticular The synovial

focal in distribution The environment of the patient should be determined with regard to exposure to extremes of temperature and humidity as well as to prolonged hours of work undue fatigue or severe mental shock It is important to know about repeated trauma of one kind or another to the joints The dietary habits of the patient can best be determined by a well trained dietitian However, since there is evidence to show a relationship between dietary deficiencies and diseases of the musculoskeletal system, physicians may obtain some information relative to deficiencies after careful analysis of the patient s eating habits absorption and utilization of food etc See Chapter 14

The development of the history of the present illness should include such details as the date of onset of muscular atrophy or paralysis, bone tenderness and pain in or about a joint The description of the joints should mention the degree of swelling tendency to disappear and recur, and distribution Most patients with chronic illness especially joint disease, have tried various remedies before consulting the physician It is advisable therefore to include these in the history

A detailed physical examination must be made The posture, gait, habitus and general attitude of the patient should be recorded Examine the ears for tophi the skin for subcutaneous nodules and the various joints for tender or swollen bursae Search for foci of infection Determine whether the patient has a tendency to bruise easily and look for minute hemorrhages in the skin and beneath the finger nails Atrophy of the muscles and power of contraction should be noted The color and temperature of the skin about a joint the degree of moisture of the palms of the hands and feet the tenderness of the bones and muscles may give details of information that may be of value in differential diagnosis

In making the diagnosis of musculoskeletal disease, one must when possible include certain laboratory procedures When anemia is encountered an accurate estimation of the hemoglobin and enumeration of the red blood cells is indicated The total white blood cell count and the filament and non filament differentiation aid in determining the degree of activity of a given process Estimation of the rate of sedimentation of the erythrocytes becomes a valuable laboratory aid in the study of patients with rheumatoid arthritis A determination of the blood uric acid, the Wassermann reaction and the gonococcus fixation test are of help in differentiating puzzling cases of swelling of the joints In recent years a technic has been devised for the growth of gonococci on special media Roentgen ray examination of at least one of the involved joints or bones should be made Removal of synovial fluid for culture and cell count, and biopsy of synovial membrane muscle or bone are other procedures which may prove of aid when wisely chosen

SPECIFIC INFECTIOUS ARTHRITIS
*(Organism Known)*

GONORRHEAL ARTHRITIS OR GONORRHEAL RHEUMATISM —In the past it has been estimated that as many as 5 per cent of the persons infected with the gonococcus develop gonorrheal arthritis The initial infection need not be the usual genital one It may be proctitis or extragenital or even an ophthalmia Since the introduction of new drugs (sulphonamide and its derivatives and penicillin) and fever therapy in the treatment of this disorder the incidence of the articular complications has fallen to less than 0 5 per cent

Rheumatism associated with gonococcal infection may show considerable difference between the time of infection and the onset of symptoms and display considerable variation in its manifestations For consideration of gonorrheal arthritis see Chapter 5

CHRONIC GONORRHEAL RHEUMATISM

This condition may closely simulate rheumatoid arthritis There is a polyarthritis involving the interphalangeal carpal and carpo metacarpal joints as well as the joints of the knees and feet Pain and tenderness of the volar surface of the calcanei frequently are present There is a tendency to fibrosis contracture and ankylosis as is found in rheumatoid arthritis

An unusual feature of gonorrheal arthritis

Predisposing causes are exposure fatigue and exhaustion or physical and emotional shock such as grief and worry The onset may follow any exhausting disease

Foci of infection have long been held as etiologic factors in rheumatoid arthritis The tonsils sinuses middle ear gall bladder and prostate have been reported to be the sites of infection Contrary to expectations there was found to be no lessening of the arthritis following their eradication An objection to the theory pertaining to focal infection in arthritis could be made on the ground that such focal infection sometimes is found upon close study in persons who show no signs of arthritis Mention should be made that arthritis may be seen to develop rapidly in cases of infection with retention of pus The writer recalls an incidence wherein a physician was suffering from infection about the root of a tooth His ankles and knees suddenly became swollen red and painful Adequate drainage of the tooth socket was established serosanguineous pus exuded and the joint swelling disappeared spectacularly This is clearly an example of infectious arthritis

Whether or not rheumatoid arthritis is a manifestation of tissue sensitivity or allergy to some bacterial infection or to food is still a matter for further investigation This hypothesis would presuppose that an allergen absorbed into the blood-stream from some focus of infection or from the intestinal contents would have the power to sensitize synovial tissue Perhaps the presence of allergy in a susceptible individual may play a role in acute joint swelling but it is difficult to apply this to a state of chronic swelling

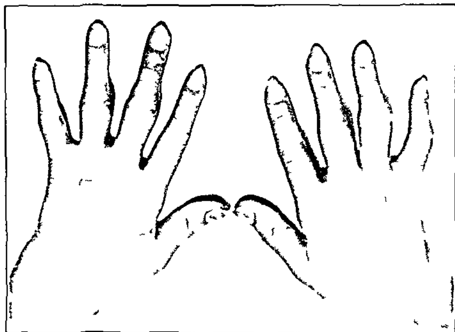

FIG 215 —Rheumatoid arthritis showing swelling of the metacarpophalangeal joints Note fusiform swelling of proximal interphalangeal joints

There is evidence to show that an abnormality of the nervous system is present in rheumatoid arthritis Almost invariably there is marked sweating of the hands and feet This is not to be accepted as the usual suderesis and the cooling off process associated with a febrile condition but rather as a localized sign of instability of the vasomotor system Blanching of the fingers is another example of involvement of the nervous system This phenomenon with its appearance suggestive of Raynaud s disease is frequently seen and found to precede the development of arthritis The atrophy of muscles the thin waxy appearance of the

fluid usually is serous in quality and may become purulent

A transitory phase of joint swelling occasionally accompanies such infections as Haverhill fever puerperal fever influenza, scarlet fever, mumps chronic ulcerative colitis and erysipelas The joint manifestations are largely symptomatic and in almost all instances there is a complete return of joint function

Should the effusion become septic surgical drainage may be indicated

ARTHRITIS OF RHEUMATIC FEVER

*Rheumatic Fever* —Since joint pain and swelling are well known to be a part of the symptomatology of rheumatic fever they will be given brief consideration here

The larger joints are usually affected first the knees ankles shoulders and wrists apparently being the more vulnerable ones However there may be involvement of the elbow joints and hips, and the smaller joints of the feet and hands There may be a monarticular or polyarticular distribution throughout the body A striking feature of rheumatic arthritis is its tendency to shift from one joint to another Wherein one articulation may be affected suddenly all signs of inflammation will subside to reappear in one or more other joints

Pain is the outstanding symptom The joints are tender to the touch and slight pressure is sufficient to make the patient wince or cry out The overlying skin usually is slightly reddened but not invariably so There may be slight or considerable evidence of synovial swelling, and accordingly the tumefaction may be soft firm or fluctuant, depending upon the degree of tension

The histologic examination may reveal the joint cavity to be the site of an acute inflammatory process Klinge described the changes in detail, he stated that there is a hyperplasia of the synovial epithelium within and upon which are streaks of fibrinoid necrosis, the connective tissue appears edematous and is infiltrated with leukocytes a hyaline fibrinous material is to be seen free in the joint space

There is some experimental evidence to show that these pathologic changes are strikingly similar to those found in the joints of scorbutic guinea pigs Rinehart and Mettier produced chronic scurvy in guinea pigs and subjected them to superimposed infection (beta streptococcus) An arthropathy appeared which was considered to be fundamentally similar in character and distribution to that of rheumatic fever Of considerable interest in this connection is a statement by T Duckett Jones who observed that epistaxis and splinter hemorrhages beneath the finger nails are a frequent accompaniment of rheumatic fever Large doses of vitamin C administered to patients with rheumatic fever have acted to prevent this phenomenon and caused the hemorrhagic tendency to disappear

RHEUMATOID ARTHRITIS

*Synonyms* — Atrophic Non suppurative arthritis deformans Chronic infectious arthritis Proliferative arthritis

*Definition* —A disease of the joints of unknown etiology characterized by an inflammatory reaction in the synovial membrane and periarticular structures effusion in the joint cavity and atrophy of the regional bony and muscular structures Early in the course of illness there is pain and stiffness due to swelling and muscle spasm Later there is deformity and loss of joint function due to ankylosis The disease tends toward chronicity and a polyarticular symmetrical distribution

*Incidence* —At present there are no accurate figures concerning the incidence of rheumatoid arthritis

Rheumatoid arthritis is found more frequently in women than in men It occurs with great frequency in the temperate zones the geographic distribution of this disease is the same as that of rheumatic fever It is world-wide in distribution but is infrequent in the tropical and sub tropical climates

*Etiology and Pathogenesis* —The cause of rheumatoid arthritis is unknown Whereas some investigators consider it to be infectious in origin others regard it as due to a deficiency in certain vitamins the result of altered metabolism or possibly to an abnormality in endocrine function

brilliantly eosinophilic hyalinized fibrin

*Symptoms and Course of Illness*—The onset of illness may show extreme variations Individual susceptibility and resistance to the disease are evident Very little emphasis has been placed on the insidiousness with which rheumatoid arthritis may develop Occasionally patients are seen who complain of weakness lassitude and rather vague and fleeting joint pain There may be few or no signs of inflammation After some weeks or months stiffness and slight swelling make their appearance in a number of the small joints especially the carpal joints *These signs tend to disappear and recur repeatedly* Eventually the changes become increasingly severe and finally are persistent

In other patients the beginning may resemble an attack of acute rheumatic fever Extreme prostration a high fever at the onset rapid pulse moderate leukocytosis enlargement of the spleen and generalized adenopathy all denote an infectious process As the disease progresses it becomes distinguishable from rheumatic fever by its symmetry in distribution and the periarticular changes which are more in evidence and more permanent in nature

The smaller joints of the extremities the wrists and ankles are usually the first to become involved swelling on the dorsal surface of the metacarpal bones stiffness and weakened grip of the hand may be noted Involvement of the interphalangeal joints shows a quite characterisic picture There is a fusiform swelling of the middle joints due to an excess of synovial fluid periarticular edema and infiltration The patient finds it difficult or impossible to close his hand The metacarpophalangeal joints and the metatarsophalangeal joints may also become involved in the process Eventually the elbows shoulders knees spine the sacro iliac and acromioclavicular joints and not infrequently the articulation of the jaw show evidence of the disease

In the acutely involved joints there is redness heat extreme tenderness and pain Over a period of time the redness and pain may subside but the heat and tenderness persist In the gradually advancing cases the findings are less pronounced the joints may seldom show redness but the tenderness may be acute and of diagnostic significance

The course of illness in some instances is subacute After a period of weeks or a few months some of the joints clear up and are restored to usefulness A tendency toward spontaneous remission exists and although every joint in the body may have been crippled at one time the signs of an acute inflammatory process subside Under these circumstances the function of some joints will return but others will suffer permanent loss of function as a result of the inflammatory sequels

The chronic form of illness is most frequently *encountered by the physician* Following the inflammatory phase in the joints, or coinciding with it the characteristic atrophy of muscles appears In a few instances the atrophy may precede the *joint swelling Loss of function* occurs in muscle groups about an involved joint and is usually symmetrical

As time goes on contracture of unapposed muscles makes an appearance fibrosis ankylosis and destruction of cartilage progresses in the joints and varying degrees of disability appear In the hands the fingers assume an ulnar deviation The stresses of contracture and the loss of cartilage produce sharp flexion of some of the terminal phalanges The disability may be accentuated by subluxation of the middle phalanges Power to flex and extend the hand at the wrist is lost early because of fusion of the metacarpal bones Movements requiring coordination of muscle such as supination of the hand flexion and extension of the forearm elevation and rotation of the humerus are lost and contribute to the disability of the patient In the lower extremities similar structural changes occur, and when marked in the toes ankles and knees the patient becomes bedridden and helpless

In the *slowly advancing cases of rheumatoid* arthritis loss of weight is apparent and the patient becomes rapidly emaciated The atrophy of muscles loss of subcutaneous fat and thinning of skin over the *joints all accentuate the swelling of periarticular* and joint structures Loss of appetite flatulence constipation low blood pressure weakness and hypochromic anemia contribute to the patient s general debility

skin, the brittleness of the finger and toe nails, and thinness of the cortex of bones may be other indications of trophic changes wrought through influences of the nervous system.

Some mention should be made of the altered psyche in patients with rheumatoid arthritis. Mental depression, loss of interest in environment, utter hopelessness with regard to the future, and abandonment of the will to help oneself are attitudes seen in arthritic patients.

In summing up the available data on the etiology of rheumatoid arthritis it appears that the disease usually manifests the characteristics of an infectious process. Fever, leukocytosis, rapid sedimentation rate, and signs of inflammation in the synovia suggest this possibility. The finding of agglutinins and precipitins for streptococcus in the blood in a high percentage of patients offers strong evidence for this bacterium as the source of the disease. The sequence of events resulting in structural changes possibly depends upon local sensitization of joint structures, low plasma ascorbic acid, and influences resulting from damage of the organic or functional nervous system.

The possibility that some biochemical disturbance resulting from endocrine dysfunction might be at fault in the pathogenesis of rheumatoid arthritis becomes likely in view of the recent publications of Hench and his associates on the favorable effect of Compound E (Cortisone acetate) on the rheumatic state.

*Pathology*.—In recent years much has been added to the knowledge of the synovial fluid and the synovial membrane in health and in disease. The works of Allison and Ghormley, Coombs, Kling and Bauer and his associates are among the more important contributions on this subject, and in them is to be found a more adequate concept of the structural changes of the synovial membrane in rheumatoid arthritis.

The synovial sac is distended and increased in size due to effusion of synovial fluid. The quantity that may be aspirated from a knee joint may vary from as little as 15 cc. to as much as 150 cc. It appears more or less turbid. Cell counts done on the fluid from a large series of cases were found to average from 10,000 to 20,000 cells per cu. mm. The percentage of polymorphonuclear leukocytes is high in the majority of cases. The fluid usually gives an alkaline reaction to litmus and shows a positive reaction for mucin.

The most constant finding in the synovial membrane in rheumatoid arthritis is a proliferative reaction. The synovial villi are thickened, there is a lymphocytic infiltration of the tissues, and there is some evidence of fibroblastic hyperplasia. A fibrinous material intermingles with tongue-like outgrowths resulting from proliferative reaction and extending into the joint cavity and over the articular surfaces to form a pannus. The organization of this fibroid material leads to the development of ankylosis.

The periarticular tissues are also involved in the process. Analogous changes are present in the connective tissue beneath the synovial membrane and in the tendons inserting around the joint. Edema, infiltration with lymphocytes, increased numbers of connective tissue cells and hyaline streaks of fibrin all add to the swelling, deformity and limitation of movement of the joint.

Retrogressive changes are apparent in the articular cartilage. Areas of destruction and necrosis may be seen. Attempts at repair are recognized elsewhere by undifferentiated and at times vascularized connective tissue. There is a general thinning of the cartilage and subjacent bony trabeculæ. As the cartilage undergoes absorption and fibrous replacement, calcification or ossification of this fibrous tissue takes place. The center of the end portion of the bone shows absorption in irregular areas. The new bone formation is more active toward the periphery.

Interesting subcutaneous nodules are found in a high percentage of patients. They usually are felt beneath the skin about the joints, but occasionally are encountered attached to an underlying bony structure. These nodules show the histologic characteristics of the rheumatic granulomas. On microscopic examination the tissue seems to be edematous and made up largely of a cellular fibrous tissue in the interstices of which may be seen irregular strands of

kyphosis The arms hang loosely from the rigid spine and the patient acquires a waddling gait

The most valuable aid in the diagnosis of rheumatoid arthritis of the spine is the appearance of the changes in the roentgenographic film In the sacroiliac joints the changes may vary from narrowing of the joint which is an early sign, to irregular proliferation of the margin and osteoporosis of the adjacent bone and signs of complete ankylosis The most important joints to be examined are the apophyseal joints Until recently they have been given little attention (Fig 217) Special oblique views are necessary to demonstrate any changes Here again the early finding may be that of narrowing or clouding of the joint spaces In far advanced cases the common finding is that of calcification of the anterior and lateral ligaments

The treatment of rheumatoid arthritis of the spine requires the combined efforts of physician orthopedist roentgenologist and physiotherapist At present the most valuable means of preventing the advance of the disease is *x* ray directed down the entire length of the spine The technique generally used in our clinic is as follows In people of average length four portals are placed longitudinally along the vertebral column a single field placed horizontally to cover the sacroiliac joints The most superior field measures 10 by 10 centimeters and the others 10 by 15 centimeters In shorter people the spine is easily covered by three 10 by-15 centimeter portals placed longitudinally the sacro iliac port is transversely situated as before The fields are delineated with indelible skin marking ink so that the treatment cone may be placed identically each time This inked boundary of adjacent portals results in separation of the fields by from 5 to 7 millimeters

Fig 217 —Marie-Strumpell spondylitis of cervical vertebræ

Under these circumstances the sedimentation rate is increased, there is slight leukocytosis and a moderate elevation of temperature

Patients may suffer from little pain while exhibiting advanced stages of the disease When the signs of inflammation have subsided the periarticular skin may continue to show *an elevation of temperature* In the presence of cold damp weather there is apt to be a return of pain and temporarily increased stiffness especially at night seen in some joints, and fibrosis, loss of cartilage and ankylosis are seen in others

RHEUMATOID SPONDYLITIS SPONDYLITIS *DEFORMANS* (*SPONDYLOSE RHIZOMELIQUE*, MARIE-STRUMPELL DISEASE) —Spondylitis deformans is a manifestation of rheumatoid arthritis in the vertebral column and its ligamentary attachments It may be confined to the spinal column or appear as part of a generalized rheumatoid arthritis

Early in the disease there is limitation of motion of the lumbar or cervical spinal segments due to pain and muscle spasm The disease progresses and finally all of the verbebræ are involved There is fixation of *the spinal column which may* be almost complete due to ossification of the ligaments and bony ankylosis The ribs become fixed the chest flattened and the entire spine may be totally rigid *There is frequent* involvement of the hips and shoulders (rhizomelique) although these joints often escape

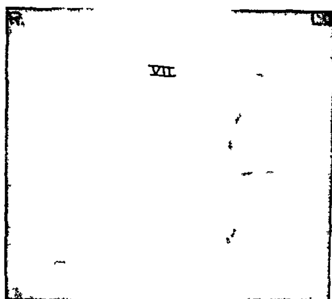

FIG 216 —Rheumatoid Spondylitis

The *roentgen ray examination* of the patient may reveal no abnormalities in the joints in the early stages Fusiform effusion in the interphalangeal joints giving rise to *soft tissue swellings may be noted* before any change in the density of bony structure is discovered Among the early changes is rarefaction of the trabeculated ends of the bone The *zone of calcification* however is preserved The joint space will be widened along with the effusion Later the joint space is narrowed and atrophy of the bone ends is evident *Finally there is* generalized decalcification, but reparative calcareous lipping will persist Enlarged punched out areas of bone atrophy appear, these are commonly encountered in *rheumatoid* arthritis as well as in gouty arthritis Deformity due to softening and subluxation of bone may be

On examination in the early stages of the disease the spine may appear straight The presence of an abnormality may be detected only after careful examination for muscle spasm or the fixation of two or three vertebræ As ankylosis of the vertebræ progresses the spine bends and the stature of the patient shortens due to marked

acerbations and remissions rather than to a steady progression of symptoms The terminal phalangeal joints of the fingers and toes are more frequently involved and usually are symmetrical The nails of the fingers and toes show changes usually found in psoriasis Atrophy of the bone may be extreme in these cases of psoriatic arthritis

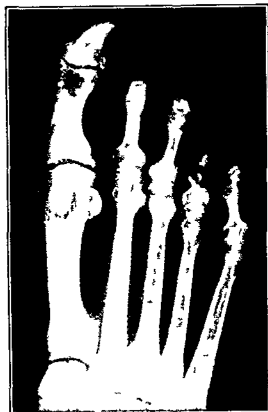

Fig 218 —Psoriatic arthritis There is a loss of bony substance of the terminal phalanges

Reiter's Disease —This disease is characterized by arthritis involving one or more joints and associated with urethritis conjunctivitis and keratinizing skin lesions A number of cases have now been reported and so far have been limited entirely to males The joint swelling may last for a period of weeks or months and tends to undergo relapse followed by remission So far no specific bacteriologic agent has been isolated

Palindromic Rheumatism —Palindromic rheumatism is thought by some to be a true syndrome but by others to be an unusual form of rheumatoid arthritis The clinical manifestations consist of repeated afebrile attacks of acute or subacute arthritis accompanied by pain swelling redness and disability A single joint is usually involved only rarely are there evidences of the inflammatory process in multiple joints The onset of illness is usually abrupt it lasts for a few days only completely disappears and then recurs at varying intervals It appears in adults of either sex There are no laboratory tests of diagnostic value

*Differential Diagnosis* —The differential diagnosis of rheumatoid arthritis is seldom difficult in patients with a slowly progressive form of the disease In patients with an acute fulminating arthropathy associated with fever leukocytosis and red swollen joints the resemblance to rheumatic fever is so close that differentiation is difficult Soon however the acute phase subsides and there appear the periarticular changes which characterize the chronic form of the disease

The differentiation from degenerative joint disease (osteo-arthritis) is set forth in table 63

It is important to emphasize the fact that rheumatoid arthritis and degenerative joint disease may occur in the same individual A person in the fifth or sixth decade with osteophyte formation of the knees may show a superimposed rheumatoid arthritis

Rheumatic fever relatively afebrile and running a subacute course may simulate rheumatoid arthritis This is especially true in ambulatory patients The distinction becomes clear when the patient develops signs of mitral valvulitis or periarthritis Valvulitis is not a feature of rheumatoid arthritis however we have observed several cases of mitral stenosis and insufficiency in patients with spondylitis deformans

Gonococcal arthritis may be readily mistaken for rheumatoid arthritis in women without evidence of vaginal discharge A history of exposure to possible infection may be denied The diagnosis will rest largely on the possibility of obtaining cultures of the gonococcus from the cervix the bloodstream or the joints involved A strongly positive gonococcus complement fixation test will aid in the diagnosis A history of shaking chill may be diagnostic of gonococcal bacteriemia whereas this phenomenon seldom occurs in rheumatoid arthritis

Using $x$-rays generated by 200 kilovolts constant potential H.V.L. 1.05 millimeters copper, 50 centimeters target-skin distance, and an output of approximately 45 roentgen a minute, 200 roentgen (air) are delivered to the upper and lower halves of the vertebral column and paraspinal musculature on alternate days for a total of 600 roentgen (air) per field.

For treatment of a chronic inflammatory lesion on the surface, it is desirable to deliver from 75 to 150 roentgen to the process at each treatment. For surface lesions, beams of "softer" quality are adequate, but in order to deliver the same dose at the depth with which we are concerned, it is felt that a beam of the quality described is more appropriate. The 200 roentgen (air) is equal to 263 skin roentgens on the 100 square centimeter field and 273 skin roentgenograms on the 150 square centimeter fields. At the average depth of 7 centimeters the calculated tissue dose, therefore, is 121 roentgen and 134 roentgen respectively.

After a rest period of four weeks, a second identical course of treatment is given, and after a second rest period of twelve weeks, the third and final course of treatment is administered.

From twenty-four to forty-eight hours after the first exposure, the patient will experience relief. The mode of action of the roentgen ray in relieving pain in rheumatoid arthritis is not understood, but it is felt that it causes a dissolution of the inflammatory process and has a tendency to lessen muscle spasm. Treatments are given daily for a period of one week, followed by a rest period of four weeks. Then a second course of treatment is given; this is followed by a rest period of three months before the third and final course of treatment is given.

Exercises to regain lost range of motion of the spine should be conducted under supervision of the physiotherapist. This may best be done after exposure to radiant heat followed by massage, passive exercises and then active exercises which will tend to cause forward flexion of the spine. The importance of a proper posture must be stressed and all patients instructed in exercises to maintain a normal stance and strengthen the back muscles. Deep breathing exercises should be resorted to three times daily in an endeavor to increase the movement of the thoracic cage.

This method of treating rheumatoid arthritis of the spine has been used in our clinic since 1941 with gratifying results. There have been very few failures, and in most of these there has been alleviation of symptoms after a second course of therapy.

## Miscellaneous Types of Rheumatoid Arthritis

**Juvenile Rheumatoid Arthritis (Still's Disease).**—In 1897 Still described cases of arthritis in children associated with splenomegaly, adenopathy and leukopenia. Since then other cases have been reported in the literature. The histologic changes in the lymph nodes and spleen have not been considered specific for any disease. The course of illness, the tendency toward bony ankylosis and muscle atrophy are comparable to those in adults.

**Rheumatoid Arthritis of Adults With Splenomegaly, Adenopathy, Anemia and Leukopenia (Felty's Syndrome).**—Felty in 1924 reported a group of five cases of chronic arthritis in patients with leukopenia and splenomegaly. Curtis and Pollard compared the clinical findings and histologic changes in cases of Felty's syndrome with those of rheumtaoid arthritis with splenomegaly and leukocytosis and another group with rheumatoid arthritis but without splenomegaly or leukopenia. They found that the pathologic reactions in the spleen, lymph nodes and bone marrow were nonspecific.

**Rheumatoid Arthritis With Psoriasis (Psoriatic Arthritis, Psoriasis Arthropathica).**—The occurrence of psoriasis with rheumatoid arthritis has been the subject of discussion in approximately 200 cases reported in the literature. Some authors maintain that psoriatic arthritis is a separate disease entirely; others believe the combination of skin and joint changes to be a matter of coincidence. There are certain clinical features, however, that differ from the usual ones found in rheumatoid arthritis. There is a tendency toward ex

active process in approximately 50 per cent of cases treated with chrysotherapy.

Before outlining my plan for the treatment of rheumatoid arthritis it may be well to discuss a failure which is directly due to the physician himself. Most articles dealing with the treatment of arthritis emphasize the need for rest. Taken literally, the patient is placed in bed and his wants cared for without so much as the elevation of his hands. After months of bed rest the feet become rotated outward from pressure of the bed clothes, the knees are fixed and the arms held rigidly to the sides of the body. Thus the patient becomes an abject figure and totally disabled as a result of the prolonged inactivity.

The treatment of rheumatoid arthritis should be carried out systematically and with careful attention to many details.

The activity of the process must be gauged and methods of treatment employed to meet the individual case; this applies to rest, muscular activity, diet, physical therapy and medication.

In general the patients may be divided into groups—those ambulatory and those requiring bed rest. In so far as possible and with due caution for their health we encourage patients to be ambulatory and busy. This helps to keep up their morale, maintain muscle tone and prevent ankylosis.

The patient requiring bed rest is usually emaciated and suffering from exquisite pain on motion of the joints. Fever, slight leukocytosis and moderate anemia may be present. Rest for this type of patient should be relaxing in so far as possible. The bed should be firm in order to avoid sagging. The weight of the blankets must be kept off the feet of the patient by draping them over a wooden frame support or pillows tucked in at the foot of the bed. Sand bags or partial casts may be employed to keep the extremities in good alignment and to reduce muscle spasm. One or more times daily each joint should be gently flexed and extended to break down fibrous growth and prevent ankylosis. The use of splints and casts for the purpose of immobilization is to be discouraged. The application of such apparatus promotes ankylosis and permanent disability of a joint.

Adequate nutrition must be maintained. Gain in weight in undernourished patients is usually a sign of improvement, whereas loss in weight offers a grave prognosis. A total intake of from 2000 to 3000 calories should be encouraged, depending upon the size of the patient. Milk, fruits, meats and fish are indicated. Pemberton believes there is increased absorption of carbohydrates from the intestinal tract in patients with rheumatoid arthritis and accordingly advocates the avoidance of too much starch. Rinehart has shown there is a decrease in the utilization of vitamin C in patients with this disease. An adequate supply of vitamin C may be insured by drinking 400 to 600 cc. of fresh orange juice daily. The orange juice may be supplemented by ascorbic acid preparations (i. e. cevitamic acid 0.050 three times daily). Added vitamin concentrates A, B and D may aid in regaining the general nutrition of the patients.

Effecting the relief of pain arising in the joints, especially during the acute phase, becomes a problem for the physician. There is reason to believe that the salicylates not only relieve pain by their inherent analgesic action but exert some influence in lessening inflammatory edema in the tissues as well. Salicylate of soda or acetylsalicylic acid when used in large doses, 10 grains (0.6 gm.) may be followed by considerable amelioration of symptoms. The total dosage for twenty-four hours may be from 45 to 90 grains (3 to 6 gm.). Medication should be so spaced that the patient will have a higher concentration of the drug in the hours prior to bedtime in order that it may reasonably assure a good night's sleep. Gastric upsets from the drug may be curtailed by taking bicarbonate of soda or by use of enteric coated tablets. Sedatives such as codeine or other opium derivatives should never be used on account of addiction. Small doses of whiskey may be used instead.

Since 1925 there has been slow but gradually increasing interest shown in the use of gold salts, gold and sodium thiosulfate in aqueous suspension (gold sodium malate) are the most popular preparations. Reports in the literature are somewhat at variance with regard to total dosage. Most authors

Tuberculous arthritis may offer difficulty in differential diagnosis. Failure to demonstrate a primary tuberculous infection in the lungs or elsewhere leads to greater difficulty. Tuberculous arthritis is usually monarticular and local radiation of heat is often more marked than in rheumatoid arthritis. It may be necessary to resort to biopsy of the synovial membrane and animal inoculation before a positive diagnosis can be made.

TABLE 63

| | *Rheumatoid Arthritis* | *Degenerative Joint Disease* |
|---|---|---|
| Onset | Acute, progressive, with or without fever | Insidious, afebrile |
| Age | Any age, usually 20 to 40 years | After 40 years |
| Sex | Females 2 to 1 | Equal in both sexes |
| Weight | Underweight | Overweight |
| Joints involved | Any joint in body, usually symmetrical fusiform swelling of fingers | Spine, knees, fingers (Heberden's nodes) |
| Muscle atrophy | Marked, symmetrical | Absent or slight |
| Contractures | Marked, symmetrical | Absent |
| Disability | Frequently complete ankylosis in some joints, marked limitation by contracture and luxation | Partial through osteophytes and lipping |
| *Anemia* | *Moderate to marked* | *Coincidental* |
| Roentgen ray findings | Widening of joint space early, later atrophy of bone, obliteration of joint space | Osteophyte formation, lipping of bone, seldom atrophy of bone |
| Sedimentation of red blood cells | Rapid | Normal |

TABLE 64

| | *Rheumatic Fever* | *Rheumatoid Arthritis* | *Pyogenic Arthritis* | *Intermittent Hydrarthrosis* |
|---|---|---|---|---|
| Pressure | Increased | Increased | Increased | Increased |
| Viscosity | Slightly increased | Increased | Increased | Normal |
| Leukocytosis | Total count up to 25 000 cells, polymorphonuclear | Up to 15 000 cells, polymorphonuclear and monocytes | Up to 20 000 cells, polymorphonuclear | No increase |
| Globulin | Increased | Increased | Increased | Normal |

disease becomes spontaneously inactive after a few months, leaving little or no disability. In other patients, irrespective of treatment, the disease progresses steadily or by periods of relapse alternating with remission, resulting in widespread ankylosis of the joints and permanent disability. Generally speaking, the disease is not inconsistent with longevity, even in well advanced cases. Patients seldom die from any direct effect

Rheumatoid arthritis must be distinguished from intermittent hydrarthrosis. In this relatively benign form of chronic villous arthritis there may be slight or no constitutional symptoms. The knees are usually the only joints to become involved.

Examination of synovial fluid may be of aid in the differential diagnosis. A few examples are set forth in table 64.

*Prognosis.*—The prognosis *in rheumatoid* arthritis is variable. In some patients the

of the disease itself. Once the joints are involved, the prognosis becomes a matter of estimating the degree of disability or the return of function to the joints affected. Restoration of function to a joint cannot be expected after the cartilage has been destroyed and extensive fibrosis has occurred.

Contractures and deformities may be prevented by proper orthopedic support and the aid of a suitably trained physical therapeutist. There is hope of arresting the

active process in approximately 50 per cent of cases treated with chrysotherapy

Before outlining any plan for the treatment of rheumatoid arthritis it may be well to discuss a failure which is directly due to the physician himself Most articles dealing with the treatment of arthritis emphasize the need for rest Taken literally the patient is placed in bed and his wants cared for without so much as the elevation of his hands After months of bed rest the feet become rotated outward from pressure of the bed clothes the knees are fixed and the arms held rigidly to the sides of the body Thus the patient becomes an abject figure and totally disabled as a result of the prolonged inactivity

The treatment of rheumatoid arthritis should be carried out systematically and with careful attention to many details

The activity of the process must be gauged and methods of treatment employed to meet the individual case this applies to rest muscular activity diet physical therapy and medication

In general the patients may be divided into groups—those ambulatory and those requiring bed rest In so far as possible and with due caution for their health, we encourage patients to be ambulatory and busy This helps to keep up their morale maintain muscle tone and prevent ankylosis

The patient requiring bed-rest is usually emaciated and suffering from exquisite pain on motion of the joints Fever slight leukocytosis and moderate anemia may be present Rest for this type of patient should be relaxing in so far as possible The bed should be firm in order to avoid sagging The weight of the blankets must be kept off the feet of the patient by draping them over a wooden frame support or pillows tucked in at the foot of the bed Sand bags or partial casts may be employed to keep the extremities in good alignment and to reduce muscle spasm One or more times daily each joint should be gently flexed and extended to break down fibrous growth and prevent ankylosis The use of splints and casts for the purpose of immobilization is to be discouraged The application of such apparatus promotes ankylosis and permanent disability of a joint

Adequate nutrition must be maintained Gain in weight in undernourished patients is usually a sign of improvement whereas loss in weight offers a grave prognosis A total intake of from 2000 to 3000 calories should be encouraged depending upon the size of the patient Milk fruits meats and fish are indicated Pemberton believes there is increased absorption of carbohydrates from the intestinal tract in patients with rheumatoid arthritis and accordingly advocates the avoidance of too much starch Rinehart has shown there is a decrease in the utilization of vitamin C in patients with this disease An adequate supply of vitamin C may be insured by drinking 400 to 600 cc of fresh orange juice daily The orange juice may be supplemented by ascorbic acid preparations (*i e* cevitamic acid 0 050 three times daily) Added vitamin concentrates A B and D may aid in regaining the general nutrition of the patients

Effecting the relief of pain arising in the joints especially during the acute phase becomes a problem for the physician There is reason to believe that the salicylates not only relieve pain by their inherent analgesic action but exert some influence in lessening inflammatory edema in the tissues as well Salicylate of soda or acetylsalicylic acid when used in large doses 10 grains (0 6 gm ) may be followed by considerable amelioration of symptoms The total dosage for twenty four hours may be from 45 to 90 grains (3 to 6 gm ) Medication should be so spaced that the patient will have a higher concentration of the drug in the hours prior to bedtime in order that it may reasonably assure a good night's sleep Gastric upsets from the drug may be curtailed by taking bicarbonate of soda or by use of enteric coated tablets Sedatives such as codeine or other opium derivatives should never be used on account of addiction Small doses of whiskey may be used instead

Since 1925 there has been slow but gradually increasing interest shown in the use of gold salts gold and sodium thiosulfate in aqueous suspension (gold sodium mallate) are the most popular preparations Reports in the literature are somewhat at variance with regard to total dosage Most authors

advocate the injection of 25 to 50 mg at intervals of one week

The response to treatment may be gauged by a recession of signs of activity pain swelling local heat, fever, a return to normal of the sedimentation rate and by a general feeling of well being on the part of the patient According to the various reports these gratifying results may be expected to occur in from 50 to 80 per cent of patients so treated It may be necessary to give a third or possibly a fourth series of injections In our clinic we have adopted the plan of giving continued treatment to patients showing favorable results On the basis of these results injections are given at intervals of one month with the hope of preventing relapse

In about one-third of the patients receiving this treatment there will be evidenced a mild degree of dermatitis, and in a few patients a severe exfoliative dermatitis Purpura hemorrhagica granulocytopenia, nephritis, hepatitis may be observed, and some fatalities have been reported Examination of the urine before each injection and frequent examination of the blood are indicated

As part of the program to build up the general health of the patient foci of infection should be sought for and so far as practicable removed The tonsils paranasal sinuses gums tooth sockets gall bladder cervix and prostate should be carefully investigated and if found to be infected eradication by proper surgical procedure should be instituted Nevertheless the patient must not be led to believe that a cure will result from such a procedure

Physical therapy must be utilized as an adjunct to the medical treatment of rheumatoid arthritis This includes heat, massage passive and controlled exercise baths and a pool When properly used such measures aid primarily in the relief of pain control of muscle spasm increase in peripheral blood flow, prevention of muscle atrophy and in rehabilitation of the patient

The beneficial effect of heat on arthritic joints is well known For centuries sufferers from rheumatic pain have sought the relief afforded by natural hot springs, spas or elaborate baths In modern hospitals containing physical therapeutic equipment a variety of methods are available for promoting heat as a means of reducing pain and inflammation in the joints, these include infra red ray heat cabinets diathermy short wave baking heat pads and fever therapy

A skilled physical therapeutist can do much to prevent the development of deformities During the acute phases of pain and swelling the institution of gentle passive motion may inhibit formation of adhesions and prevent or correct contractures The loss of muscle tone and its subsequent atrophy may be minimized by massage In the later stages of the disease the correction of those deformities which may be overcome is sometimes surprising

Orthopedic measures should be employed A properly applied support to an acutely swollen joint will afford rest and relief of pain Great caution should be taken however to prevent ankylosis from prolonged inactivity Systematic exercises of muscle groups should be carried out at regular intervals throughout the day to prevent atrophy Following the acute stage removable supports may be fitted to the afflicted joints to aid the patient in becoming ambulatory or to correct contractures Braces are an essential support to the spine for the correction of kyphosis in a patient with spondylitis Occasionally surgical intervention becomes necessary to reduce contractures or possibly to free fibrotic tissue in or about a joint

In patients who are anemic, transfusions of whole blood may be the quickest and best means of restoring the red blood cells and hemoglobin to normal levels When hypochromic anemia is present iron medication (ferrous sulphate 0 3 gm three times daily) is indicated

## The Place of Cortisone and ACTH in Rheumatoid Arthritis

By John Lansbury M D

The recent introduction of Cortisone and ACTH in the management of rheumatoid arthritis has opened a new chapter in the experimental therapy of arthritis and has stimulated great interest in the possible role of steroid hormones in the pathogenesis

of the arthritides While it is too early to see the place of Cortisone in true perspective the following points are emerging —(1) Cortisone and Compound F are unique among the available steroids in their antirheumatic effect (2) This anti rheumatic effect is in no way specific but is part of a general suppressive action on a wide variety of unrelated non rheumatic diseases (3) The action of Cortisone is suppressive palliative protective and temporary It does not cure arthritis or any other disease and must for the time being be regarded as symptomatic therapy

The dramatic beneficial effects which occur immediately after the administration of cortisone or ACTH in rheumatoid arthritis must not be confused with the problem of the indefinite administration of these substances in what is generally a life long disease So far we have only a few observations on the effect of these agents on rheumatoid arthritis over a period of a year and none at all on their effect after 3 5 or 10 years Even short term administration of cortisone and ACTH is sometimes attended by undesirable and even serious side effects These are more apt to occur however in patients over 40 years of age It is probably too early to state the indications for ACTH and Cortisone therapy in arthritis Obviously they are contraindicated in the 'burnt-out' end stages of the disease Also they are contraindicated in the early cases which might respond well to gold therapy If they really have a place in treatment it would seem to be in those cases which are rapidly getting worse despite all other forms of therapy The case of moderate severity in which the patient has adjusted to his disease is best left without the false hope which Cortisone gives Short courses of Cortisone as an adjunct to straightening of knees by traction may find a place The average dose of Cortisone should not exceed 50 mg per day and both patient and doctor should accept partial rather than complete releif as their goal For this reason it is wrong to start off with large doses which give complete relief which cannot be safely maintained on a long range basis

Cortisone and ACTH are contraindicated in case of impaired myocardial function hypertension potentially psychotic personality peptic ulcer sickle cell anemia malaria and pulmonary tuberculosis

Potentially serious side effects of the agents are hydremia transient hypertension a tendency to thrombosis, hypokalemic alkalosis, delayed healing, accentuation of diabetes mellitus and alternating states of mania and depression In long-continued cortisone or ACTH therapy there is theoretically, danger of pituitary and/or adrenal cortical atrophy and lowering of thyroid function (as judged by the reduction of protein bound iodine levels of the blood and reduced radio active I uptake) There is also danger of increased serum-cholesterol levels with the possibility of premature atherosclerosis (as seen in spontaneous Cushing s syndrome) and perhaps osteoporosis There is some evidence of a decline in response to both ACTH and cortisone over a long period

Annoying but not necessarily serious side effects have been reported as follows renal glycosuria obesity increased tendency to infection salivation changes in auditory function (impairment or increased acuity) blurred vision weakness acne moon face of Cushing s syndrome and a tendency to fractures in old people a tendency due either to increased activity or to an increase in osteoporosis

Cortisone and ACTH if warranted at all in the treatment of rheumatoid arthritis should certainly be reserved for rapidly progressing cases that have failed to respond to other measures (such as gold therapy) Patients receiving these agents should have their sodium intake limited to 200 mg a day should receive additional potassium in the form of either potassium acetate or chloride (in doses of from 1 to 5 grams a day) should note their daily basal weight in order to detect early water retention and should have a weekly record of blood pressure until their pressor response is known to be within safe limits An electrocardiogram and a determination of the sodium and potassium levels of the blood may also be of value in detecting potassium depletion and sodium retention

The hydremia by far the most common complication may be partly controlled by the program given above Diuretics in the

form of ammonium chloride and mercurials (the latter used *periodically*) may assist in controlling the water retention Some authors mention the use of thyroid substance and of estrogens and testosterone to help combat some of the side effects but further observation is required before these can be regarded as standard therapeutic agents Electroshock therapy may reverse the depression sometimes caused either by cortisone administration or by cortisone withdrawal

There is reasonable hope that modifications in the technique of administration of Cortisone and of Compound F or perhaps the use of synergistic drugs may eventually permit the use of much smaller doses so that the undesirable side effects of these steroids *may be lessened to the extent of making* their long range use in arthritis safe and satisfactory

In their present state they must be regarded as experimental rather than as an established therapy

## Degenerative Joint Disease

*Synonyms* — Hypertrophic arthritis Osteo arthritis

*Definition* — Osteo arthritis is an arthropathy of unknown etiology, principally affecting *middle-aged or elderly persons* The joint deformity results from loss of cartilage and absorption of bone hypertrophy with lipping and osteophyte spur formation at the joint margins

*Etiology* — There are perhaps many factors which contribute to the joint changes in osteo-arthritis The process of aging itself renders changes in the bony tissues that make them less resistant to the stresses and strains to which they commonly are subjected

Vascular degeneration with its diminished blood supply, osteoporosis and loss of elasticity of cartilage break down the resistance of the tissues to trauma and postural strain Perhaps these changes may be considered metabolic in nature and it may be that infection does not enter into the production of this disease Hypertrophic changes sometimes are found in joints as a late manifestation of traumatic gouty, hemophilic gonorrheal or rheumatoid *arthritis* and may be considered as secondary changes

Since no infectious agent has been found as the causative principle and since the joint changes are *not those typical of an inflam*matory reaction, it hardly seems consistent to use the term "arthritis" in referring to this condition The American Rheumatism Association recommends the term "osteoarthritis", therefore, it shall be used here in accordance with their classification The term degenerative joint disease would seem to bear more relevancy as a classification for this particular group

*Pathology* —The changes characteristic of osteo arthritis develop slowly over a long period of time Bennett, Waine and Bauer have *studied the histological development* of the disorder in a series of 60 presumably normal knee joints They found the earliest trace to be present in the third decade of life The cartilages most likely are first to show the process of degeneration Early there is absorption of central areas of the cartilage or about the periphery and later the cartilage may be entirely absorbed An attempt at repair is visible in the formation of small amounts of fibrous tissue and spongy bone structure At the edges of the joint bony formation is more advanced and there are *rounded prominences of spongy* bone covered by cartilage These take on the appearance of lipping or spur formation The ends of the shaft of the bone become porous and its articular surface is eburnated and polished

In the periarticular structures there is little or no evidence of the inflammatory swelling so characteristic of rheumatoid arthritis However ossification which presumably is part of the degenerative process may be seen in the tendinous insertions and in the ligaments and bursæ The skin seldom shows any change The synovial membrane may be thickened especially about the periphery Within the synovial cavity fragments of bone or cartilage may break off or be eroded off to form loose bodies These are the so-called *joint mice* Ankylosis of a joint does not occur but there may be locking of a joint due to loss of cartilage and the interference of its

motion due to lipping or spur formation

The study of the distribution of these pathologic changes throughout the body is of interest The spine knees and hips are most often affected These are the weight bearing joints and those most subject to postural strain In the terminal phalangeal joints may be found bony enlargements which are pathognomonic of hypertrophic arthritis These are known as Heberden s nodes

A rough estimate has been made that 90 per cent of the general population over fifty years of age show some evidence of hyper trophic arthritis The processes are seen during routine roentgen ray examinations and more often than not are asymptomatic Their presence usually is unknown to the patient A very small percentage of individuals may complain of symptoms arising from hypertrophic joint changes

*Osteo-arthritis (Degenerative Joint Disease) of the Cervical Vertebræ* —In recent years a syndrome characterized by pain about the neck and in the shoulder girdle has been the subject of considerable discussion In the medical literature one finds such conditions designated as radiculitis pain of nerve root origin neuritis or the radicular syndrome as described by Gunther and Kerr

Mettier and Capp studied a group of patients with symptoms characteristic of cervical arthritis The symptoms com plained of most frequently were pain rigidity of the neck and muscular weakness of the hand or arm The onset of pain was usually abrupt and in many cases was first noticed by the patient on awakening in the morning More often than not the pain was localized in and about the shoulders especially about the insertion of the deltoid muscle or it radiated down the arm into the fingers As a rule these symptoms ap peared months or even years before there were any complaints of discomfort in the region of the neck Usually the pain is *unilateral but with* the exception of a few instances it becomes bilateral at some time during the progression of the pathologic condition The pain varies from that of an excruciating character to a dull aching sensation At times it is described as sharp jabbing needle like and penetrating at other times as a prickly or stinging feeling Some patients complain only of numbness and tingling in the fingers or of a drawing or dead aching sensation in the muscles of the arm

The loss of freedom or use of one upper extremity is a common complaint Many patients become unable to comb their hair or to extend the arm behind the back to adjust their clothing Others are unable to perform fine movements such as sewing or writing and some of them find it difficult to grasp objects

A few patients become conscious of pain in the neck during the early course of illness but in most patients it is a late development In no instance is there definite restriction of movement of the head and neck but it is often stated that pain in the neck may be induced by jarring of the body The dis comfort is sometimes described as a head ache at the base of the brain as a feeling of ' congestion at the base of the brain or simply as muscular soreness

There is no evidence of atrophy of the muscles of the hands arms or shoulder girdle The reflexes of the arm show normal reactions

Roentgenographs taken of the cervical vertebræ should include exposure of the oblique as well as the usual anterior pos terior and lateral projections Hypertrophic changes from slight to marked may be observed such changes as circumferential osteophyte formations These project into the intervertebral canals from the superior or inferior margins of the vertebræ and cause narrowing of the foramina Osteo-arthrosis occurs more frequently on the left side than on the right In addition the intervertebral disks are usually thinned out in the region of exostosis It is an interesting fact that the sites of predilection are distributed between the fifth and sixth and the sixth and seventh vertebræ X-ray findings may be minimal at first and appear more striking after symptoms subside

In the differential diagnosis one must give consideration to such conditions as trau matic injury to the brachial plexus or to pressure on this structure by cervical ribs or hypertrophied scaleni muscles (scalenus anticus syndrome) actual destruction of the

vertebra by bacterial agents or neoplastic metastasis, and traumatic arthritis of the shoulder joint and bursitis

*Hypertrophic Spondylitis* —Evidences of osteo arthritis also may be found in the thoracic vertebræ but especially in the lumbar vertebræ A ring of osteophytes around the joint gives the characteristic roentgen ray picture There is relatively little pain accompanying these changes although occasionally there may be radiculitis There is never the complete ankylosis of the Marie Strumpell type have considerable difficulty in going up and down stairs Aches and pains in the ham string the gastrocnemius and peroneal groups of muscles frequently bring forth complaints

There are relatively few findings on physical examination Slight swelling of the afflicted knee may be apparent the changes are usually more pronounced in one knee than the other but may be symmetrical There is slightly increased warmth of the skin, but this is not as pronounced as in rheumatoid arthritis On careful examina-

FIG 219 —Degenerative joint disease hypertrophic arthritis of cervical vertebræ

*Osteo-arthritis of the Knees* —The symptoms arising from hypertrophic arthritis of the knees usually come on slowly In the early stages there may be slight pain and stiffness but as the process becomes more advanced pain and stiffness become increasingly severe The symptoms are most marked when the patient begins to move about after a period of rest On arising from bed or on attempting to get up from a chair action in the knee joint is inhibited by pain and stiffness After limping about and exercising for a short time the symptoms subside and the patient may resume a fair degree of activity These patients usually tion of the joint margin with the palpating finger definite points of tenderness may be localized A grating sensation or crepitation may be felt when the palmar surface of the hand is placed on the patella and the leg flexed or extended on the thigh

Examination with the roentgen ray will reveal many characteristic findings Degeneration of the cartilage is discernible and narrowing of the joint space is apparent Irregular destruction and hypertrophy of the marginal bone is seen evincing a picture of bony overgrowth lipping and spur formation

*Osteo-arthritis of the Hips (Hip joint disease of the aged Morbus coxæ senilis Malum coxæ senila)* —Osteo-arthritis of the hips it may be truly said is an excellent example of degenerative joint disease Trauma incident to obesity or external blows is a most important precipitating factor Often on careful questioning it is elicited that the patient had sustained an injury of one sort or another to the hip joint years before the onset of symptoms This type of joint disability is not infrequently seen in patients with Paget s disease

The structural changes in the joint are largely consistent with a loss of cartilage, especially in the weight bearing regions There is eburnation of the surrounding bone Fixation of the joint may result from roughening of the articular surface and flattening of the head of the femur As the process advances the fossa of the acetabulum becomes enlarged and deepened

The onset of symptoms comes on insidiously The patient may first experience some stiffness and pain in the thigh At this stage an erroneous diagnosis of 'sciatica may be made After a period of weeks or months a limp becomes noticeable and pain is induced by motion Pain and disability progress and become outstanding symptoms The patient finally resorts to the use of a cane seldom to crutches

Shortening of the leg occurs as a result of the narrowing of the joint space and becomes further accentuated by the deepening of the acetabulum The patient assumes a stooped posture He walks with a rolling limping gait and depends upon his cane for considerable support

On examination atrophy and spasm of the regional muscles are observed Motion of the joint is limited in all directions There is usually no impairment of the reflexes

Examination of the roentgen ray film discloses narrowing of the joint space however there is little or no evidence of cartilage In the surrounding bone increased density is seen due to eburnation The characteristic changes of osteo-arthritis are apparent about the joint margins where lipping and spur formation have taken place

*Heberden s Nodes* —Heberden s nodes are bony swellings which appear at the terminal phalangeal joints They are usually symmetrical and not associated with pain Some discomfort may be noticed because of interference in freedom of motion of the joint or soreness resulting from trauma to the vulnerable projections In a well advanced case there may be some angulation and fixation of the terminal phalanx

This condition is readily differentiated from rheumatoid arthritis In the latter, the middle interphalangeal joint is usually involved and shows the characteristic fusiform soft tissue swelling The bony outgrowths at the terminal phalanges are frequently confused with gout especially in the minds of the laity Tenosynovitis or localized bursitis may simulate the Heberden s node Such foci of tenosynovitis will show evidences of an inflammatory reaction Heat, redness and tenderness are sufficient findings to make a differential diagnosis

*Menopausal Arthritis* —A definition of ' menopausal arthritis will not be attempted here because there is insufficient evidence to indicate that this is a clinical syndrome however some observers believe the disturbance is primarily endocrine in origin

During the menopause women not infrequently become conscious of pain and aches in or about the joints An early manifestation may be an audible creaking sound when the patient kneels On examination the knee joints are most often observed to be affected The regional findings are those characteristic of osteo-arthritis Occasionally there may be hypertrophy of the synovial villi and effusion in the synovial sac Most women are overweight in a degree disproportionate to their bony and ligamentous structure as a result there may be evidences of joint strain in the feet ankles hips and back Pes planus puffiness about the ankles stiffness in the hips and poor posture also may be found in varying degrees

*Treatment* —Middle aged or elderly patients complaining of stiffness and pain in or about the joints repeatedly come to the physician with the conviction that they are about to become hopelessly crippled from arthritis Should the symptoms prove to arise from osteo-arthritis (degenerative joint disease) it is important to acquaint the

patient with the nature of his condition He should be informed that this is an infirmity which is mainly the result of the aging process and of repeated trauma to the articular structures through joint strain It should not be confused with the disability found in connection with progressive ankylosis of the joints as manifested in rheumatoid arthritis Reassurance of the patient that he will not progress to total disability is often enough to bring forth the expression, I feel greatly relieved already! A person beyond the age of fifty to whom it is explained that he or she is approaching middle age usually will understand these changes

Patients with osteo-arthritis should not be encouraged to remain in any fixed position for a long period of time In osteo arthritis of the knees and hips prolonged sitting promotes muscle spasm and stiffness Periods of rest alternating with exercise should be planned Elevation of the legs or flexion and extension of the legs on the thighs at frequent intervals is often sufficient to keep the lower extremities limbered up

Relief of pain is essential An analgesic drug such as acetylsalicylic acid when properly used is often sufficient to produce satisfying results This drug will relieve pain when given in divided doses so that the patient receives from 3 to 4 grams throughout a twenty four hour period Patients who are freed of these painful symptoms will regain confidence and the courage to use their extremities However caution must be observed in giving large doses of acetylsalicylic acid to elderly patients with cerebral arteriosclerosis occasionally a drop in blood pressure may occur

Obesity is frequently encountered in patients with osteo arthritis of the knees (menopausal arthritis) and hips and is an indication for reduction in weight

Various mechanical supports for the joints may be required Elastic supporters for the knees, braces for the hips and back will be found valuable A board under the mattress to avoid bowing of the springs may help to correct back strain

Relief of pain and stiffness may come from the use of physical therapy in the form of heat and light massage Baking diathermy or such simple household procedures as the application of wet packs or a well covered hot iron to the involved joint may prove effective The patient, or a member of the household can be taught to massage gently the articular structures Alcohol warm oil, or a liniment (equal parts of methyl salicylate and chloroform liniment) may serve as an external lubricant

Patients with hypertrophic spondylitis will require particular attention and instruction Correction of posture becomes paramount and can best be done by a trained physical therapeutist This applies not only to lumbar strain but to cervicodorsal kyphosis as well In cervical osteo-arthritis gentle manipulation of the vertebræ and manual traction may be beneficial in addition to massage

### Arthritis of Immediate Traumatic Origin

Traumatic joint disease may result from a single blow or fall, or from repeated slight trauma to the articular structures Disability may occur immediately or not until months or years have elapsed following the initial injury

In acute traumatic arthritis joint function is disturbed as a result of sudden torsion or a blow such as may be experienced in playing football or in a fall The knee joint is most frequently involved There may be an internal derangement resulting from damage to the semilunar internal or lateral cartilages The knee joint becomes locked and synovial swelling soon appears Sprain of the ligamentous supports of the knee or other joints may produce tears and coincidental rupture of blood vessels with hemorrhages in the tissues A common form of acute traumatic arthritis results from injury to a distal phalanx Rubbing of an elongated nail of the big toe against the shoe stubbing the toe against a fixed object or a blow from a baseball on the end of a finger may induce sufficient concussion to injure the delicate synovial tissues

In the chronic form of traumatic arthritis the initial injury which produced transient disability and seemed entirely inconsequential at the time may reappear months or even years later when the patient will

become aware of the insidious development of pain and stiffness

Often the symptoms may come on so insidiously or at a period so far distant from the original trauma that the patient may completely fail to recall an injury or do so with some difficulty Other inceptive causes may be a blow to the shoulder sustained in an automobile accident a fall down stairs striking the coccyx (coccygodynia) or repeated sprain of a wrist or ankle leading to chronic changes

*Definition* —Gout is presumably a disturbance of purine metabolism The clinical manifestations are characterized by severe pain in articular structures and the formation of tophi It is a chronic condition with a tendency to acute attacks

The history etiology pathologic physiology and treatment are considered in the section on diseases of metabolism page 505

*Course of Illness* — The first attack of gout usually appears at the site of the metatarsophalangeal joint of the great toe and most

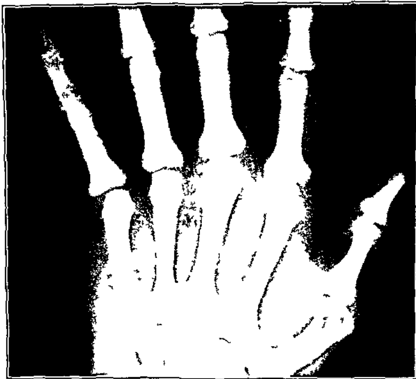

Fig 220 —Gout Note punched out areas in terminal portions of proximal phalanges

The structural alteration in affected joints is essentially that of osteo arthritis Loss of cartilage lipping and spur formation are *the characteristic findings*

It may be mentioned here that trauma may be a precipitating factor in other types of joint disease

## Arthritis of Gout

*Synonyms* — Gouty arthritis Podagra Metabolic arthritis

often is monarticular However the instep heel ankle knee and in rare instances the fingers or wrist may show the first signs of the disease Pain is the outstanding symptom noted by the patient and usually appears suddenly at night At the onset it is dull and aching in character but after several hours it becomes a constant and excruciating aching sensation The surrounding soft tissues are red and swollen and the regional veins are dilated The joint is extremely sensitive to touch or pressure The reaction of the

initial attack begins to lessen after two or three days. The hyperemia subsides, the tissues become less sensitive and painful but a moderate degree of edema persists.

Following the first attack of gout there may be a recurrence of the illness in from two weeks to as long as two years. With the passage of time there is a tendency for the attacks to occur at more frequent intervals.

Clinically, a chronic state of gout is recognized. The patient is usually obese, but may be thin, he has a florid complexion and is reputed for his excesses in fatty foods, red meats and wine. The insatiable desire for rich, highly seasoned foods often becomes acute just prior to a flare up of joint symptoms. One or more tophi are seen on the auricula of the ears. There is persistent slight swelling, redness and tenderness of the involved joint. There even may be bony ankylosis. The roentgen ray picture usually is unmistakable. Deposits of sodium urate crystals may be seen in the cartilages and synovia. There may be marked destruction of the cartilage. Bony overgrowth and spur formation is not an unusual finding. In the region subjacent to the cartilage bone is absorbed and replaced by gouty deposits appearing as dense rounded shadows on the film. These punched out areas are 3 mm or more in diameter and are characteristic of advanced gouty arthritis.

Swelling of the olecranon bursa is frequently seen in chronic gout.

Although these changes are more or less paramount the patient may follow the pursuit of his duties relatively free of symptoms when there will be a sudden and acute exacerbation of joint swelling accompanied by pain. Such episodes may be precipitated by trauma. Overexercise and sweating, chill or swimming in cold water may bring on an exacerbation. It is not unusual for an attack of gout to appear within a few hours after a surgical operation. Just prior to the attack the patient develops a craving for fatty food and is irritable and cranky. Gout is always a chronic condition with a tendency to acute attacks (Hench).

## Arthritis of Neuropathic Origin

*Synonyms* —Charcot's joint. Trophic arthritis.—In untreated syphilitic patients with tabes dorsalis, a type of arthropathy occasionally is seen. The first clinical description was given by Charcot in 1868.

The knee joint is most frequently involved. The changes are essentially trophic in nature. There is marked absorption and disintegration of bone irregularly distributed throughout the portions entering into the formation of the joint. Adjacent to such areas there

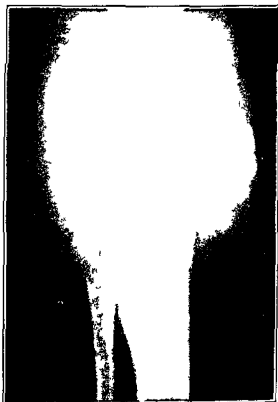

Fig 221 —Charcot's joint

is new bone formation. The process of destruction and the building of new bone give the joint certain characteristics that render these changes clinically recognizable. There may be enormous enlargements of the bony outline of the joint causing the joint to feel like a sac of bones. Ankylosis does not occur. The skin overlying the joint is thin and glossy.

Pain is sometimes experienced, but characteristically there is lack of pain or tenderness. The patient exhibits hypermotility of the joint to a marked degree without experiencing discomfort.

Syringomyelia shows arthropathies of a somewhat similar nature wherein the shoul

der and elbow frequently are involved Both syringomyelia and tabes affect the feet

Arthritis due to nerve injury or in connection with hemiplegia or chronic encephalitis may be of varying types

## Neoplasms of Joints

Neoplastic processes arising from joint structures are relatively uncommon

Osteochondroma —This is a relatively benign swelling which may appear along the joint margin or at the distal end of a bone It is most often seen in persons between twenty and fifty years of age The symptoms are relatively mild, usually in the form of an aching sensation Pressure or soreness from trauma may attract the patient's attention to a small palpable, hard swelling The histologic examination reveals a chondromatous mass in which there are areas of calcification and ossification These small tumors usually may be detected by the roentgen ray and are recognized by a bony projection through the periosteum the tip of which is covered by cartilage

Synovioma — *Synonyms* —Fibrosarcoma Synovial sarcoma —The synovioma is a sarcomatous degeneration of the synovial membrane Cases occurring in early infancy and the aged have been reported in the literature The tumor may be slow growing and relatively benign or highly malignant A dull aching pain and joint swelling are the outstanding symptoms It is monarticular in distribution The tumors are not sensitive to the roentgen ray Radical excision must be resorted to The prognosis is poor

## Miscellaneous Forms of Arthritis Associated With Other Diseases

Intermittent Hydrarthrosis — *Synonyms* —Chronic villous arthritis Chronic synovitis —This is a chronic disorder of the joints usually the knees and is characterized by a gradual onset of stiffness and swelling with a tendency to remissions and exacerbations

*Etiology* —The evidence for a specific infectious agent as the cause of this disorder is less convincing than for other forms of arthritis Various forms of bacteria have been isolated from the synovial fluid of these joints including the Brucella abortus however none seems of etiologic significance It appears most often in persons between the ages of twenty and forty five There does not seem to be an hereditary factor Although the disease occurs in both men and women some authors believe it to be of more frequent occurrence in women Trauma apparently is not a factor

*Pathology* —The reports concerning the histologic changes in this condition are few in number The synovial villi become elongated and hypertrophied The tissues appear edematous and there may be an infiltration with lymphocytes In the late stages some of the synovial fringes may become broken off and are seen as foreign bodies in the joint space There is little or none of the cartilaginous degeneration or pannus formation so characteristic of rheumatoid arthritis

*Symptoms* —The knee joints are most frequently involved, but evidences of intermittent hydrarthrosis may appear in the metacarpophalangeal and interphalangeal joints The onset of symptoms is gradual At first the patient is conscious of stiffness in a single or in symmetrical joints Swelling gradually appears and slowly progresses until the synovial sac is well distended The patient complains of discomfort and later of considerable pain Signs of inflammation local redness and heat are lacking but there is no fever or leukocytosis There is interference of the functional ability of the involved joint due to its being markedly swollen

The attack may last for several weeks before the effusion disappears The swelling may subside completely or there may be a permanent residual of swelling Subsequent attacks may occur at intervals of several weeks or months

After repeated attacks the patient becomes subject to permanent disability due to the proliferation and marked excess of villous tissue in the joint cavity

Roentgenograms show widening of the

joint space The bones show little or no change the outline of the bone remains smooth and clear within the joints and the cartilage is not obliterated

*Treatment* —Analgesic drugs may relieve the pain but will have no effect on the progress of the disease Rest is indicated in order to minimize trauma to the joint

Elastic supporters applied to the knees help to support the legs and suppress further effusion

It is reported that surgical treatment has given good results the joint is opened and the redundant synovial tissue removed Favorable results have also been recorded following roentgen ray therapy to the joints

HEMOPHILIC ARTHRITIS —*Synonym* —Hemarthrosis —One of the relatively frequent complications of hemophilia is the tendency to hemorrhage into the joints The clinical aspects of hemophilic arthritis have been reviewed by Key Keefer and Myers Recently, McDonald and Lozner reported on the roentgenographic findings in hemophilic arthritis Two stages are recognized (1) acute hemarthrosis and (2) the stage of healing chronic hemophilic arthritis

In *acute hemarthrosis* there is rapid swelling of the joint due to extravasation of blood within the capsule Rather severe pain accompanies the distention of the synovial sac and function of the joint is inhibited depending upon the degree of swelling The overlying skin is not red and there may or may not be slight increase in local heat The knees hips fingers and toes are the joints most frequently involved

A history of trauma sprain or torsion to the joint usually is elicited The patient is subject to repeated attacks involving the same or other joints This abnormality

FIG 222 —Hemophilic arthritis There is loss of cartilage ankylosis of the joint and marked atrophy of the bones

usually appears in the hemophiliac during childhood but has been reported in the fifth and sixth decades There is a decreasing tendency toward hemarthrosis with age presumably due to the accompanying lessened activity

The roentgenograms merely show distention of the joint cavity

The *treatment* consists of absolute bed rest and protection of the joint from motion or further trauma

Following the acute attack absorption of the suffused blood may occur leaving comparatively little disability

In *chronic hemophilic arthritis* there is a tendency to repeated hemorrhage into a single joint Due to failure of complete absorption of the blood there are evidences of attempts at organization and repair Fibroblastic proliferation is apparent and ankylosis of the joint results Accompanying this phenomenon there is some periarticular swelling and muscle atrophy becomes marked The joint becomes permanently enlarged and tender to the touch Contractures of the muscle develop and the extremities become deformed

In the roentgenograms the early changes are characterized by destruction of cartilage the appearance of spurs at the margin of the joint and slightly increased periarticular density As the process advances there is slight narrowing and irregularity of outline of the joint space Cysts appear in the subchondral tissue Finally there is marked narrowing of the joint space the articular surface is irregularly indented and the ends of the bones become deformed and decalcified There is marked subchondral cystic formation

Chronic Septic Joints —Chronic septic joints are due to localization of bacteria in or adjacent to a joint itself These foci are usually secondary metastases of organisms from elsewhere in the body The process is characterized by tissue destruction and usually the formation of pus Chronic draining from the sinuses may develop The causative agents are usually the tubercle typhoid and colon bacilli rarely are they staphylococci gonococci streptococci meningococci or pneumococci

The Oidium coccidioides (coccidioidal granuloma) may invade the bony tissues about an articular surface The infection simulates tuberculosis The spores enter the blood stream from foci in the lungs or soft tissues and invade the bones There is much destruction of tissue followed by the formation of a chronically draining sinus

*Madura foot* is endemic in India however 30 cases have been observed in North America The lesions involve the soft parts and bone especially of the foot The causative organism is thought to be a fungus

Allergic Arthritis —Acute swelling of a joint is not uncommon as an accompaniment to serum sickness Many joints may become involved especially the knees elbows wrists interphalangeal and shoulder joints Effusion into the synovial sac occurs rapidly and causes considerable pain The joints may show marked swelling or redness and are exquisitely tender These manifestations of abnormal reaction to serum usually subside spontaneously and rapidly

As a rule other signs of serum sickness are present such as urticaria and a high eosinophil count

Sedatives injections of adrenalin and cool applications applied locally may aid in relieving the patient s discomfort

structures or muscular aponeuroses in regions where pressure may come to bear on nerve bundles or trunks. Sir Thomas Lewis demonstrated a radicular type of pain that followed the injection of sterile salt solution in ligamentous and tendinous attachments to the vertebral processes. When the lower cervical or upper thoracic segments were irritated, the pain induced closely simulated that of angina pectoris. Recently Inman and Saunders stated that damage to ligamentous structures in connection with the lumbar vertebræ could act as a focus of irritation to the related nerve bundles and give rise to the sciatic radiation of pain.

Although fibrositis may not be generally accepted as a distinct entity, the results of some experimental work are beginning to appear in the medical literature establishing the relationship between ligamentous structures and radiation of pain over the course of the nerve trunks. The origin of fibrous tissue hyperplasia may in some way be related to congenital, traumatic, infectious, postural and other agents.

*Treatment.*—The immediate treatment is essentially symptomatic and is centered on giving the patient relief. The salicylates, sodium salicylate or acetyl salicylic acid, offer the greatest benefit. Such drugs are of value not only for their analgesic effect but because they tend to reduce swelling as well.

Local heat (hot packs, infra red rays), radiant heat (carbon filaments) or diathermy helps relieve pain. Massage or muscle stimulation by faradic current or other physical therapeutic measures may be indicated to overcome joint stiffness and to prevent contractures.

Measures to relieve postural strain, prevent trauma, and improve the patient's general health should be given proper consideration.

## Localized and Special Forms of Fibrositis

Localized hyperplasia of fibrous tissues may be encountered in connection with various diseases and in various locations throughout the body. It is not uncommonly seen in patients with rheumatoid arthritis and other conditions affecting the locomotor system.

Special forms of fibrositis may be classified as follows:

- Palmar fascia—*Dupuytren's contracture*
- Fibrous reticulum of the panniculus adiposus—*panniculitis*
- Nerve sheaths—*perineural fibrositis*
- Joint capsule—*capsular rheumatism*
- Fibrous tissue of muscle bundles of sheaths—*intramuscular fibrositis (interstitial myositis, muscular rheumatism, myalgia)*
- Bursæ—*bursitis*

## Dupuytren's Contracture (Fibrositis of the Palmar Fascia)

This is a common example of fascial fibrositis appearing in adults, usually at middle age although it may appear as early as the third decade. It is much more common in men than in women and it is usually found in one hand although it may be bilateral. The course of illness is gradual and after a period of time the local findings are characterized by contracture of the palmar fascia causing flexion of two or three fingers on the ulnar side of the hand. The fascia becomes adherent to the skin. The fibrous nodules are palpable and may appear as an early sign of the disease. Dimpling and deep creasing of the skin are characteristic. The degree of flexion contracture increases with the passage of time and the greatest involvement is shown in the little finger. The intensity of contracture decreases with each finger as the radial side is approached; the index finger is seldom affected.

The cause of this regional fibrositis is obscure. Treatment is surgical.

## Panniculitis.—*See* Chapter 11

## Bursitis

The bursæ are small sacs widely distributed wherever friction between muscle bundles and tendons occurs. They are made essentially of fibrous tissue. The central cavity of some of these is lined with a synovial like membrane and filled with fluid. These sacs become the locus of an

## DISEASES OF THE FIBROUS TISSUES

### Fibrositis

Stockman s definition of fibrositis is "a condition of chronic inflammation of the white fibrous tissue of the fascia aponeuroses sheaths of muscles and nerves ligaments tendons periosteum and subcutaneous tissue occurring in all parts of the body, and giving rise to pain aching stiffness, and other symptoms the result of preceding general infections or of local inflammation or injuries

### Primary Fibrositis

Primary fibrositis is relatively common Its symptoms arise from a chronic inflammatory reaction within the fibrous tissue of muscle sheaths and many kinds of mesenchymatous structures It accounts for many of the conditions designated as chronic arthritis 'muscular rheumatism," peripheral perineuritis, lumbago, sciatica, 'neuralgia and some types of torticollis

*Etiology* —The cause of primary fibrositis is unknown It may first appear during the course of acute rheumatic fever or some other infectious disease having the general manifestations of a toxemia Other factors which may be concerned in the development of this little understood condition are recurrent acute respiratory infections or chronic focal infections Undue exposure to cold weather and dampness, prolonged fatigue occupational hazards, muscular and ligamentous strain and malnutrition all may play a part in producing the inflammatory reaction in the fibrous tissues

*Pathology* —According to Stockman, the structural changes are confined to the white fibrous tissue There is a proliferation of fibroblasts within the connective tissue and an absence of *leukocytic infiltration* The tissue tends to undergo organization and there is an ingrowth of newly formed capillaries These changes may be found in areas widely distributed throughout the body or restricted to certain regions After varying periods of time the inflammatory hyperplasia may subside but in most cases the reaction becomes more desmoid and permanent These fibrous indurations assume various forms Although large areas may become thickened in the lumbar aponeurosis or fascia lata they more commonly take the form of *small circumscribed structures varying in* size from a few millimeters to 1 or 2 centimeters

*Symptoms* —Pain is the outstanding symptom This may be described as a dull aching sensation sometimes constant at other times intermittent in character The activity of muscle and joint structures may be inhibited The nature of the pain and the degree of disability depend largely on the regions involved whether in relation to joints muscle fibers ligaments or nerve trunks When periarticular structures are involved the symptoms may simulate those of rheumatoid arthritis and there may be considerable disability The involvement of tendons may be recognized by muscle weakness and the finding on palpation of small hard 'pea sized nodules within the fibrous structures near the region of bony attachment Evidences of *nerve irritation* are seen in connection with hypertrophy of ligamentous

*of an intervertebral disk* may give rise to lumbar pain. In long standing cases spinal curvature results; however, there is an associated sciatic distribution of pain and the knee jerk and Achilles tendon reflexes may be depressed or absent. The characteristic finding of rupture of the contents of the disk into the spinal canal may be seen in roentgenograms taken after the intrathecal injection of lipiodol. Sacro-iliac strain may cause spasm of the lumbar muscles. Pain is relieved following the application of a well fitting belt that firmly fixes the pelvis. Spondylolisthesis, tumors of the lower segments of the spinal cord and neoplastic growths infiltrating the sciatic nerve trunk give rise to symptoms that are radicular in distribution along the ramifications of the sciatic nerve. Metastatic carcinoma of the spine, Pott's disease of the vertebræ and osteo-arthritis will be revealed by roentgen ray examination. Paget's disease and plasma cell myeloma also must be given proper consideration in the differential diagnosis.

*Treatment.*—An attempt should be made to reduce the muscle spasm. This may be accomplished by administering large doses of analgesic drugs at stated and frequent intervals. Capsules containing acetylsalicylic acid (5 gr. 0.3 gm.) combined with codeine sulphate (¼ gr. 15 mg.) may be given the patient every two to four hours depending upon the severity of the case. It may even be necessary to give two capsules for the first and second doses. (The dosage recommended here may be compounded in a number 1 capsule that is of convenient size and easy to swallow.)

Local application of heat, hot packs or hot water bottle, followed by vigorous massage help to allay mild attacks within a few hours.

Radiation by the roentgen ray may be beneficial. An acute flare up of symptoms may result from the first treatment; subsequent treatment may bring relief.

A person once having an attack of lumbago is subject to a recurrence. He should be instructed to avoid straining, stooping, heavy lifting and exposure to cold in an attempt to prevent such an occurrence. A chronic state of lumbago accompanied by persistent pain and stiffness may result from repeated recrudescences.

*Treatment* of chronic lumbago is difficult and usually requires the aid of the orthopedic surgeon.

STERNOCLEIDOMASTOID MUSCLES (*Torticollis. Wry Neck*).—In this condition the head is drawn to one side. The abnormal position is more or less fixed and permanent. Torticollis is of relatively common occurrence. The etiology is little understood. Some cases of torticollis may be functional in nature resulting from psychosomatic imbalance. In addition to fibrositis an infiltration of lymphocytes within the muscle fibers has been described.

TRAPEZIUS MUSCLES (*Trapezius Myositis*).—Trapezius myositis is characterized by pain and stiffness in the trapezius muscle on one or both sides. The pain usually is not severe and may be described by the patient as a soreness in the muscles. The pain may radiate into the suboccipital or shoulder regions.

This affection commonly occurs in association with upper respiratory infections. Repeated attacks of the common cold, chronic inflammation of the nasal accessory sinuses, especially the ethmoid, may be predisposing factors.

Local examination of the trapezius muscles reveals few findings. Motion of the neck or shoulder girdle may be limited. The muscle bundles may feel tense and pain is elicited on pressure. There may be hyperplasia of the regional lymph nodes. A few firm tender nodules may be felt deep within the muscle substance.

Local measures are important in the treatment of trapezius myositis. At first the patient may be given an analgesic drug. Heat and deep massage will aid in the relief of pain and muscle spasm. Later manipulation may be required to relieve stiffness.

EPIDEMIC DIAPHRAGMATIC PLEURODYNIA (*Devil's Grip*).—This condition is of relatively rare occurrence in the United States. A few cases have been reported in the Mississippi Valley and the state of Colorado. Recent studies indicate that coxsackie virus of type B is of definite etiologic importance.

The onset of illness is abrupt and the patient experiences severe pain in the region

inflammatory reaction which may be acute or chronic

The etiology of bursitis is usually traumatic or infectious The bursæ placed in relation to pressure bearing areas the prepatellar bursa and the bursæ of the great toes are subjected to repeated trauma and often become the site of inflammatory swelling Elsewhere the subdeltoid bursæ may give rise to symptoms during the course of an upper respiratory infection or acute exacerbations of sinusitis, or in association with the presence of a periapical abscess

Special types of bursitis have been designated, depending upon the anatomic location and the probable etiologic factor *Subdeltoid bursitis* is recognized as a clinical entity The etiology is probably a combination of muscle strain trauma and infection Elevation of the arms for long periods of time promoting fatigue and injuries from falls may be sufficient to traumatize the tissue and permit chance infection In the early stages there is excruciating pain beneath the deltoid muscle and the patient is unable to elevate his arm There is localized point tenderness As the disease progresses adhesions form between the bursæ and its related tendons Finally the shoulder joint becomes fixed When this occurs a roentgenogram may show calcification within the bursæ Not infrequently the condition is bilateral

In the treatment of the first attack of acute subdeltoid bursitis some physicians recommend the application of heat particularly diathermy Injections of procaine hydrochloride (2 per cent solution) into the affected tissues often gives rise to immediate dramatic results In some cases the patient may enjoy permanent relief in other instances there may be a return of symptoms as the effect of the anesthetic agent wears off Relief of symptoms from the inflamed sac may result from needling the bursa under local anesthesia and aspiration of the fluid At times roentgen therapy gives prompt and continued relief In chronic cases surgical excision of the calcified bursa is the method of choice

Other frequent sites of painful inflammation are the olecranon bursa 'tennis elbow 'miner s elbow prepatellar bursa house maid s knee , and the bursa of the great toe, poor man s gout occasionally, the gluteal bursa, 'weaver s bottom

## THE VOLUNTARY MUSCLES

### Interstitial Myositis, Intramuscular Fibrositis

*Synonyms* —Primary intramuscular fibrositis, Muscular rheumatism —Interstitial myositis may be defined as a non suppurative swelling and fibroplastic proliferation of the muscle sheaths or fibers It is essentially a fibrositis but clinical types are recognized depending upon the tendinous insertions of the muscle involved

Lumbar Muscles (*Lumbago*) —The onset of symptoms of inflammation of fibrous tissues of the lumbar muscles is characterized by the sudden occurrence of pain and disability Upon questioning the patient carefully it is most always learned that some form of trauma or strain preceded the attack A sudden blow to the lumbar region may be a precipitating factor Strain incident to sudden lifting of a heavy object or elevating a stuck window,' may be sufficient to tear the fibrous attachments or sheaths of the lumbar muscles Symptoms arise quite frequently after assuming a stooping posture for a prolonged period of time Frequent examples of this are seen in individuals accustomed to sedentary habits becoming engaged in home gardening

The pain may be slight but it usually is agonizing in intensity The patient finds little comfort in any position Examination of the lumbar region reveals slight elevation of the skin due to hypertrophy of the muscles Spasm is detected by the palpating fingers The muscles are hard firm and contracted The muscle tension may cause curvature of the spinal column with concavity toward the affected side Constitutional symptoms usually are absent

*Differential Diagnosis* —The symptoms indicative of perinephric abscess may simulate lumbago Generalized symtomatology fever leukocytosis and signs of toxicity are present and aid in the differential diagnosis In renal calculus colicky pain usually radiates into the groin with accompanying urinary frequency and hematuria *Rupture*

infections of the muscles that show a tendency to suppurate They may be considered primary when a locus of infection results from some local trauma or penetrating wound to the tissues The bacterial agent is usually Staphylococcus aureus

Secondary suppurative myositis is an accompaniment of infections elsewhere in the body either by direct extension or metastasis Typhoid and meningococcic abscesses chronically draining sinuses due to coccidioides and the tubercle bacillus are examples

TRICHINOSIS —The clinical manifestations of trichinosis are described elsewhere in this book After gaining entrance to the blood stream the larvae of Trichinella spiralis invade the muscle tissues The diaphragm as well as many voluntary muscles is the site of invasion During this period of dissemination there is a local inflammatory reaction as the larvae become lodged in the muscle fibers The symptoms are largely muscle soreness pain and tenderness due to edema and swelling Later the wall of the cyst becomes calcified Treatment is entirely symptomatic

## NON-SUPPURATIVE MYOSITIS

DERMATOMYOSITIS (PRIMARY POLYMYOSITIS) —Dermatomyositis is a non suppurative inflammation of the skin subcutaneous tissues and muscles The disease once recognized by the clinician will be found to be less rare than usually is supposed

*Etiology* —The cause of dermatomyositis is unknown It may appear in persons who may have been thought to be in good health and who were living under good environmental circumstances It has occurred in athletes while in training and in fine physical form On the other hand O Leary and Waisman stated that infection or other disease preceded the onset of illness in the 40 cases studied by them

*Pathology* —There is a generalized thickening of the integument Areas of hyper keratosis are seen among which may be recognized small foci of epithelial necrosis There are edema and lymphocytic infiltration of the subcutaneous tissue An inflammatory reaction is present in the subjacent muscle consisting of areas of infiltration with lymphocytes The cellular infiltrate however, may be small even with severe myositis The changes in the muscles consist of dissolution and vacuolation of striated muscle shrinking of muscle substance and loss of striation In later stages there is caking of collagenous fibers which become swollen and highly refractile and break up into shreads and bars finally fusing into a homogenous mass

*Symptoms* —The onset of illness is insidious The patient at first complains of lassitude which later progresses to weakness and general debility There is a feeling of tenseness of the skin and the facial expression becomes more or less fixed There may be edema of the eyelids The muscles of the extremities are painful on motion and sore to the touch The skin in the affected areas feels thickened and indurated The disease process gradually extends over the entire body

The spleen and liver sometimes become palpable Slight enlargement of the superficial lymph nodes has been observed Sweating slight leukocytosis and a slight remittent fever usually are present The reflex reactions usually are reduced and sensory changes sometimes appear A transient arthralgia may accompany the illness and in severe cases contracture of the joints may result

The course of illness at times is acute but usually is subacute or chronic extending over a period of many months or years Death may result in severe cases

*Diagnosis* —The diagnosis of dermatomyositis may be established on finding the characteristic histologic pattern following biopsy of tissue The condition is to be differentiated from disseminated lupus erythematosus chronic eczema, erythema nodosum periarthritis nodosum and diffuse scleroderma

*Treatment* —The treatment is symptomatic

ACTH and cortisone have been used recently in dermatomyositis These agents are capable of altering the acute inflammatory and destructive process in the muscles however permanent remission from these agents alone is considered unlikely Thorn

of the diaphragm. The pain is accentuated by deep breathing and coughing. Fever, sweating and leukocytosis accompany the illness. The patient may experience three or four paroxysms of pain over a period of *from two to four days*. The treatment is entirely symptomatic. Uneventful recovery usually occurs.

INTERCOSTAL MUSCLES (*Pleurodynia, Intercostal Myalgia*).—A relatively common form of fibrositis is found in connection with the intercostal muscles. The symptoms are characterized by pain in the region of the lower intercostal muscles frequently adjacent to the attachment of the diaphragm. The serratus magnus and the pectoral muscles may be involved. The pain is aggravated by coughing, sneezing or full inhalation. There is hyperesthesia and deep tenderness in the intercostal spaces of the involved muscle. Spasm of the muscle may be felt.

Differential diagnosis must be made from acute pleurisy. This is an infectious process characterized by fever and general signs of toxemia. On auscultation a friction rub may be heard in the involved area during respiration. In the early stages of development of herpes zoster it may be difficult to establish the diagnosis. This is usually accompanied by an eruption of vesicles and fever. In intercostal neuralgia tender points may be determined with deep pressure on the nerve trunk along its course subjacent to the corresponding rib.

## MYOSITIS OSSIFICANS

TRAUMATIC MYOSITIS (*Traumatic Myositis Fibrosa*).—Injury to muscle bundles frequently results in tissue necrosis and hemorrhage. An example of this is the popularly known "Charlie horse" of the football player. There is a sudden rupture of muscle fibers and capillaries accompanied by hemorrhage in the tissues. In some cases there may be failure of complete resolution of the process and healing may consist in the formation of fibrous tissue and its resultant organization. Such lesions tend to undergo calcification. The reason for this deposition of calcium salts is obscure. It actually may progress to the formation of bone containing islands of blood formation.

MYOSITIS OSSIFICANS CIRCUMSCRIPTA (*Calcinosis Circumscripta*).—This name is given to a condition characterized by small areas of calcification scattered throughout the skin and subcutaneous tissues.

MYOSITIS OSSIFICANS PROGRESSIVA (*Calcinosis Universalis*).—This disease is of unknown etiology. The calcium and phosphorus levels of the blood are normal. The onset may occur early in life. There is a generalized calcification in the skin, interstitial tissues, tendons, fascia and muscles. At first the abnormality appears in a few localized areas as a fibrous tissue proliferation which spreads slowly over a period of time. The fibrous masses become indurated and undergo pathologic calcification. By extension of the process, fusion of various structures by fibrosis and bony growth occurs. The ligaments and joints become immobilized. True bone formation may extend through muscle, ligament and periosteum. Muscle atrophy becomes extreme. There may be a minimal amount of pain. Accompanying this is a slowly progressive fixation of the joints of the extremities and spine. Breathing may be restricted by fixation of the ribs and ossification of the muscles of respiration. Thus the unfortunate victim of this rare malady reaches a stage of total disability. The "ossified man" of the circus is an example of this condition.

Maldevelopment of the fingers and toes (microdactylia) has been reported as a frequent accompaniment and is thought to be congenital fault.

*Treatment*.—The treatment of traumatic myositis ossificans is preventive in character. Following trauma the injured tissues should be given immediate rest. Cold compresses should be applied and the muscles bound in a compression bandage in an attempt to prevent further hemorrhage. Later radiant heat directed to the area of injury may aid in absorbing the hematoma.

When ossification occurs, local excision of the foreign tissue by surgical procedure may be indicated. Treatment of myositis ossificans progressiva is unsatisfactory.

## PARENCHYMATOUS MYOSITIS

SUPPURATIVE MYOSITIS.—This terminology is used to designate a group of

contracted pelvis The combination of these causes the subject to assume a waddling gait

Achondroplastic dwarfs are physically active and mentally alert The sexual characteristics are normal. Sexual development may even be precocious

Until recently this condition was confused with cretinism. The cretin dwarf however is inactive physically and retarded mentally

HEREDITARY DEFORMING CHONDRODYSPLASIA (*Multiple Cartilaginous Exostoses*) —This is a rare disease in which there are many cartilaginous projections and bony exostoses appearing at the diaphyses of the long bones They have their origin from the primitive connective tissue which may differentiate into either bone or cartilage The disturbance results from abnormal stresses and strain interfering with the mechanical function of the joints The disease is not progressive after puberty and is more common in males than in females There are indications that heredity is a factor in its production If local symptoms are troublesome or deformity extreme the exostoses causing trouble may be removed surgically Some of these exostoses may be the seat of malignant change

OXYCEPHALY (*Steeple Head*) —A congenital defect with premature union of cranial sutures limiting growth of the skull except in the upward direction resulting in a tall pointed skull with marked exophthalmos Cranial nerve disturbance results from pressure and optic atrophy is apt to occur

LEONTIASIS OSSEA (*Hyperostosis of the Skull*) —A symmetrical enlargement of the bones of the skull and the mandible There is an irregularly distributed increase in density of the bone and a tendency to closure of the foramina with consequent damage of nerves and blood vessels The external measurements of the skull are greatly increased but the cranial cavity is encroached upon The skull may attain a thickness of 5 cm Pressure on nerves and brain cause the symptoms of headache paralysis blindness and convulsions

This rare disease becomes apparent most often during adolescence The course is chronic and may be interrupted by remissions As to diagnosis this condition is distinctive The etiology is obscure and treatment only palliative

HYPEROSTOSIS FRONTALIS INTERNA —This is the most distinctive of a group of calvarial changes Moore termed them metabolic craniopathies In this condition newly formed cancellous bone is deposited on the inner table of the frontal bone This bony mass may be nodular or uniform in outline Neither growth nor regression has been observed during periods of study Moore found 96 examples among the roentgen-ray plates of 6 650 persons examined and 135 cases showing other types of hyperostosis of the skull Nearly all of these reported cases occurred in women The symptoms include headache obesity of the pituitary type neuralgia of the fifth nerve hemiparesis and general weakness There may be an overgrowth of hair on the chin The symptoms are indefinite but may be severe and distressing Brain tumor often is suspected in these cases

HYPERTELORISM —Hypertelorism is a developmental congenital anomaly of the lesser wings of the sphenoid bones It is of rare occurrence Greig established the identity of this condition in 1924 when he described the complete clinical and pathologic findings in the cases he studied It was he who introduced the descriptive term hypertelorism Riley, in 1933 reported the data on four patients bringing the total number of cases to appear in the literature to 13

Hypertelorism may be recognized at birth because of the peculiar facies Due to the increased growth of the wings of the sphenoid bones the eyes are widely separated and the horizontal axis of the eyes is directed in a more lateral direction than is normal Mental deficiency usually accompanies this abnormality There is a familiar tendency to the anomalies of the sphenoid bone

LAURENCE-MOON-BIEDL SYNDROME —The Laurence-Moon-Biedl syndrome is of uncommon occurrence Riley and Lisser in their report state that 77 cases have been accumulated in the literature This syndrome according to these authors is characterized by dystrophia adiposo-genitalis atypical retinitis pigmentosa mental deficiency familial occurrence and skeletal abnormal-

and his associates have found that, once the initial improvement has been obtained with ACTH and cortisone testosterone due to its anabolic effect, may be useful in restoring the muscles as functioning units

BOECK'S SARCOID —Boeck's sarcoid is a disorder characterized by the formation of areas of induration and nodules in the skin and subcutaneous tissues At times there may be some associated changes in the bones and lungs (For further discussion *see* Chapter 10)

## DISEASES OF THE BONES

SECONDARY HYPERTROPHIC PULMONARY OSTEO ARTHROPATHY (*Marie's Disease Hippocratic Fingers*) —*Secondary hypertrophic* pulmonary osteo arthropathy is a bulbous enlargement of the terminal phalanges of the fingers and toes In mild cases the swelling is commonly spoken of as clubbing of the fingers or designated as *Hippocratic fingers* Marie's syndrome is the term applied when the swelling is well advanced and there are associated changes in the larger bones of the extremities

This unusual swelling of the *terminal* phalanges is found commonly associated with bronchiectasis, congenital heart disease primary and secondary pulmonary neoplasms *mediastinal tumors* cor pulmonale abscess of the lungs and empyema In the author's experience the most marked enlargement of the fingers and toes was observed in a patient with extensive metastatic foci of carcinomatous tissue in the lungs

In mild cases the earliest signs noted may be *curvature of the nails as to both length* and breadth, parrot's beak The soft tissues gradually swell In cases which are well developed the terminal digits appear bulbous At times deposits of calcium beneath the periosteum of the fingers may be seen in the roentgenograms

The swelling is *unaccompanied* by pain or other symptoms There is no adequate explanation for the development of this swelling in the soft tissue of the terminal phalanges

### DEVELOPMENTAL DEFECTS AND MALFORMATIONS

ACHONDROPLASIA (*Chrondrodystrophia Fe talis*) —This is a dystrophy arising from premature union of the epiphyses with the diaphyses *Growth of the long bones is* inhibited and dwarfism results

*Etiology* —Heredity apparently is a factor in the production of this disorder Snoke reports an achondroplastic father and daughter the mother being normal He also reported transmission of achondroplasia in succeeding generations of families In one series 6 achondroplastic persons were found in 5 generations

*Clinical Characteristics* —Achondroplasia is a common cause of dwarfism Subjects *of this disorder are readily recognized* The person attains a height of from 3 to 4 feet The legs and arms are extremely short—disproportionately so in comparison with the torso There is an increase in the size of the *cranial vault and the basilar portion* of the skull is shortened Due to the abnormality of the cranial bones the face has a characteristic appearance The face seems abnormally broadened and flattened and the bridge of the nose is sunken The fingers are short and tridentate (trident hand) The posture is altered by lordosis and a

contracted pelvis The combination of these causes the subject to assume a waddling gait

Achondroplastic dwarfs are physically active and mentally alert The sexual characteristics are normal Sexual development may even be precocious

Until recently this condition was confused with cretinism The cretin dwarf, however is inactive physically and retarded mentally

HEREDITARY DEFORMING CHONDRODYSPLASIA (*Multiple Cartilaginous Exostoses*) —This is a rare disease in which there are many cartilaginous projections and bony exostoses appearing at the diaphyses of the long bones They have their origin from the primitive connective tissue which may differentiate into either bone or cartilage The disturbance results from abnormal stresses and strain interfering with the mechanical function of the joints The disease is not progressive after puberty and is more common in males than in females There are indications that heredity is a factor in its production If local symptoms are troublesome or deformity extreme the exostoses causing trouble may be removed surgically Some of these exostoses may be the seat of malignant change

OXYCEPHALY (*Steeple Head*) —A congenital defect with premature union of cranial sutures limiting growth of the skull except in the upward direction resulting in a tall pointed skull with marked exophthalmos Cranial nerve disturbance results from pressure and optic atrophy is apt to occur

LEONTIASIS OSSEA (*Hyperostosis of the Skull*) —A symmetrical enlargement of the bones of the skull and the mandible There is an irregularly distributed increase in density of the bone and a tendency to closure of the foramina with consequent damage of nerves and blood vessels The external measurements of the skull are greatly increased but the cranial cavity is encroached upon The skull may attain a thickness of 5 cm Pressure on nerves and brain cause the symptoms of headache paralysis blindness and convulsions

This rare disease becomes apparent most often during adolescence The course is chronic and may be interrupted by remissions As to diagnosis this condition is distinctive The etiology is obscure and treatment only palliative

HYPEROSTOSIS FRONTALIS INTERNA —This is the most distinctive of a group of calvarial changes Moore termed them metabolic craniopathies In this condition newly formed cancellous bone is deposited on the inner table of the frontal bone This bony mass may be nodular or uniform in outline Neither growth nor regression has been observed during periods of study Moore found 96 examples among the roentgen ray plates of 6 650 persons examined and 133 cases showing other types of hyperostosis of the skull Nearly all of these reported cases occurred in women The symptoms include headache obesity of the pituitary type neuralgia of the fifth nerve, hemiparesis and general weakness There may be an overgrowth of hair on the chin The symptoms are indefinite but may be severe and distressing Brain tumor often is suspected in these cases

HYPERTELORISM —Hypertelorism is a developmental congenital anomaly of the lesser wings of the sphenoid bones It is of rare occurrence Greig established the identity of this condition in 1924 when he described the complete clinical and pathologic findings in the cases he studied It was he who introduced the descriptive term hypertelorism Riley in 1933 reported the data on four patients bringing the total number of cases to appear in the literature to 13

Hypertelorism may be recognized at birth because of the peculiar facies Due to the increased growth of the wings of the sphenoid bones the eyes are widely separated and the horizontal axis of the eyes is directed in a more lateral direction than is normal Mental deficiency usually accompanies this abnormality There is a familiar tendency to the anomaly of the sphenoid bone

LAURENCE MOON BIEDL SYNDROME —The Laurence Moon Biedl syndrome is of uncommon occurrence Riley and Lisser in their report state that 77 cases have been accumulated in the literature This syndrome according to these authors is characterized by dystrophia adiposo-genitalis atypical retinitis pigmentosa mental deficiency familial occurrence and skeletal abnormal

FIG 223 —Paget s disease

FIG 224 —Paget s disease Sarcomatous degeneration with metastases in the lungs

ities The outstanding defect in development of the bones is a tendency to polydactylism

Some improvement has been reported following the administration of thyroid extract

PAGET'S DISEASE (*Osteitis Deformans*) — This is a chronic disease of the skeleton and is characterized by thickening and softening of the bones There are marked skeletal deformities shortening of the stature enlargement of the head and a tendency to pathologic fractures There may be an associated sarcomatous degeneration

*Etiology* —This condition first was described by Sir James Paget in 1877 It has become well recognized as a clinical syndrome The etiology is unknown

*Pathology* —The structural changes in Paget's disease first make their appearance in the skull tibiæ pelvis vertebræ and later the femora and humeri Circumscribed areas of decalcification appear and the involved areas become softened Interspersed irregularly between these areas the bone still retains calcium but it may appear more porous than normal There is an increase in vascularity of the tissue

The altered metabolism in the calcium chemistry of the bone results in thickening of the cortex but the structure has less tensile strength than normal In the skull the most marked changes are in the outer plate and diphlœ resulting in an immense thickening The circumference of the skull becomes greatly increased The cortex of the tibiæ becomes thickened and undergoes changes in shape The tibiæ tend to bow anteriorly and laterally The pelvis becomes broadened the femora become bent and eventually show a forward convexity With the absorption of calcium from the bodies of the thoracic vertebræ weakness ensues and collapse subsequently takes place The spine therefore assumes marked kyphosis

The pathologic changes may be complicated by the appearance of areas of sarcomatous degeneration in the bones Metastases from such areas may appear in the lungs or elsewhere in the body

*Symptoms and Course of Illness* —The onset of illness is insidious and the course a slowly progressive one Pain may be the first symptom Primarily dull and aching in character it increases in intensity with the passage of time The patients describe it as a deep constant dull aching pain Some patients however may go along for years experiencing only a minimal amount of pain

Information concerning the time of onset of the disease may be gained from inquiring into the patient's experience in buying hats It may be learned that years prior to the onset of pain or disability the patient found it necessary to buy new hats at frequent intervals because of the increasing circumference of the skull

There is a progressive kyphosis of the spine leading to marked shortening in stature As much as 10 inches in loss of height may be noted in a patient when standing

The shortened stature pendulous abdomen, large protruding head bowed shin bones and waddling gait combine to give the patient the characteristic habitus of advanced Paget's disease

The increased porosity of the bones renders them susceptible to fracture from slight trauma Tripping on the stairs or other forms of sudden contraction of the hamstring muscles against their apponens may be sufficient to cause a break of the femur Due to kyphosis fracture of the sternum is not unusual

*Diagnosis* —The roentgen ray examination reveals the osseous changes characteristic of Paget's disease In the early stages small circumscribed areas of irregularly scattered bony absorption may be seen in larger areas of density As the process of osteoporosis and intervening osteosclerosis advances shadows of increased density appear in the roentgenograms comparable to 'tufts of cotton These early changes not infrequently are observed in the roentgen films without the presence of the condition having been suspected clinically

In advanced cases the thickening of the bones become apparent The shadows cast by the trabeculæ become course and prominent In some areas the caliber of the marrow cavity may be encroached upon and narrowed elsewhere there may be widening

The roentgenograms offer little difficulty in differential diagnosis from conditions

in which the bony changes are essentially osteogenic in character As a rule it is easily distinguished from carcinomatous metastasis, multiple myeloma and osteitis fibrosa cystica

Blood chemistry determinations may be of aid in diagnosis The calcium and phosphorus levels will be within normal values but the serum alkaline phosphatase will be high

In patients with Paget s disease seen on our wards at the University of California Hospital, we have been impressed by the high incidence of nodular goiters The majority of these patients show an increased intestinal absorption of carbohydrates such as is seen in patients with goiter They also show a "low carbohydrate tolerance which is, in fact, an alimentary glycosuria In such instances the clinical picture resembles that of mild diabetes

*Treatment* —Patients suffering from pain will require analgesics Roentgen ray irradiation over painful areas may afford some relief The administration of ascorbic acid daily in amounts up to 1 gm may ease the bone pain There are no satisfactory means of treating the fundamental condition

Osteitis Fibrosa Cystica Generalisata —*In this condition multiple areas* of absorption appear in the bones followed by fibrous tissue replacement and cyst formation Fracture or bending of the long bones is of frequent occurrence For a clinical description of this condition and discussion on physiological chemistry the reader is referred to Chapter 16

Osteomalacia —This condition is characterized by a tendency to repeated fractures resulting from decalcification and increased brittleness of the bones Control studies to determine the excretion of calcium carried out according to the plan outlined by Aub show a marked increase in the excretion of this chemical, presumably it is removed from the bones Although there is evidence to show that the output is increased the blood calcium level remains at a normal value Content of phosphorus in the blood may be slightly reduced and the phosphatase activity slightly increased

The *etiology* of this condition is obscure The disease has been reported to appear most frequently in women Repeated pregnancy at frequent intervals may be a *predisposing factor* wherein the balance between deposition of calcium in the fetal bones and the bones of the mother is disproportionate Lack of vitamin D may play a role in the development of some of these cases and in this respect simulates rickets

The onset of illness is insidious Fracture may result from trivial trauma or over exertion of one muscle group against another *Roentgenograms will show the marked* porosity and rarefaction of the bones

The course of illness is chronic Some strengthening of the bones may result from intensive therapy with calcium vitamin D or cod liver oil concentrates

A word of caution is to be offered in connection with overdosage with vitamin D concentrates An elderly physician seen by us had a high calcium and magnesium *content in the kidneys and muscles through*out the body from the daily ingestion of large amounts of a preparation of vitamin D concentrate Death resulted from uremia

## Idiopathic Fragility of Bones

Hereditary Type of Hypoplasia of the Mesenchyme (*Brittle Bones and Blue Sclera*) —This condition is rare but large family groups have been traced Hill and McLanahan report characteristic signs in 27 of 51 members of five generations in a family studied by them Burch and Sodeman found 41 persons affected of 76 observed in a study of members of five generations in still another family

This seems to be a distinct clinical entity attributed to a hypoplasia of the mesenchyme transmitted as a dominant characteristic according to the Mendelian law Those affected are usually slender the scleræ show a bluish color attributed to thinness of the membrane Otosclerosis with deafness develops at an early age in a large proportion of these subjects Fractures occur throughout childhood but are not frequent after puberty Healing of fractures is not delayed and there is no undue deformity

This condition may cause little trouble in adult life No form of treatment is known

to be of value. There are reports of apparent favorable reaction from strontium lactate and calcium phosphate. Cod liver oil concentrates are recommended.

CONGENITAL TYPE (*Osteopsathyrosis; Osteogenesis Imperfecta; Lobstein's Disease; Fragilitas Ossium*).—A congenital defect of bone formation in which the bones are delicate and fragile, the cortex thin and the marrow cavity enlarged. Fractures of the bones occur on slight strain or injury. Lewin mentions a teacher aged fifty years who has had one hundred and twelve fractures and is still active in her work. This form of fragility is not shown to be hereditary; it occurs as the strictly congenital type with the bone defects developed in fetal life with death usually taking place in infancy. Or it may be due to osteogenesis imperfecta tarda wherein the appearance of symptoms is delayed. As a result calcium metabolism is disturbed. Cod liver oil, calcium and phosphorus are recommended.

SENILE OSTEOPOROSIS.—This is a systemic loss of calcium from the skeletal system. It occurs along with the physiologic and metabolic changes that characterize the aging process. Normally there is a daily breakdown and repair of osseous tissue by the osteoclasts and osteoblasts. In the aged, osteoblastic activity is lessened with a resultant failure to deposit calcium in the organic matrix. This results in a decreased calcium content of the bones.

The systemic calcification is accompanied by brittleness and softening of the bones. The bodies of the thoracic vertebra become compressed and the spine bowed, hence the kyphotic spine of age atrophy. Fracture of the bones occurs frequently. The head, neck, and shaft of the femur and the pelvic bones are most frequently the sites of pathologic fracture.

The diagnosis of senile osteoporosis usually can be established from the radiograms. The decalcification is widespread throughout the skeletal system.

The etiology of osteoporosis is not definitely known. Albright is of the opinion that the disturbance is a failure of the osteoblasts to lay down bone matrix. He discusses three factors which might influence osteoblastic activity: (*a*) steroidal hormones; (*b*) mechanical stresses and strains; (*c*) nitrogenous building blocks. The osteoporosis of old age is partly attributed to the loss of gonadal hormones and adrenal-cortical N hormone and may respond to appropriate estrogen and testosterone therapy.

It is well known that mechanical stresses and strains stimulate osteoblastic activity and the sedentary habits of the aged individual may lead to osteoporosis through atrophy of disuse.

The production of bone matrix is undoubtedly influenced by the availability of certain nitrogenous substances such as the serum albumin. In such conditions as starvation, malnutrition, and nephrosis, conditions in which the serum albumin is low, osteoporosis is common.

## CONDITIONS CHARACTERIZED BY SCLEROSIS OF THE BONES

Two types of osteosclerosis are recognized: the so-called marble bone or Albers-Schonberg disease, and myelosclerosis or myelofibrosis.

MARBLE BONES (*Albers-Schonberg Disease; Osteosclerosis Fragilis Generalisata; Osteopetrosis*).—In osteosclerosis the essential lesion is one primarily of excessive bone formation. There is gradual thickening of the cortex and encroachment on the medullary cavity. The condition occurs usually in childhood and persists throughout life into adulthood. All of the bones of the body including the vertebrae and the skull may be affected. Due to increased calcification the bones become extremely dense and of marble-like texture. When attempting biopsy of such tissues the surgeon encounters extreme resistance of the tissue against the bite of the rongeur.

Unmistakable pictures which are characterized by the dense sclerosing process are revealed in the roentgenograms.

As the thickening of the cortex progresses the medullary cavity is encroached upon and the illness may terminate with a myelophthisic type of anemia.

The etiology of this comparatively rare condition is unknown.

MYELOFIBROSIS (*Fibrosis of the Bone-marrow—Myelosclerosis*) —This type of sclerosing process usually appears after the second decade The onset of illness is insidious and may be characterized by deep bone pain or tenderness The patient may consult his physician because of some symptom referable to an abnormality in hematopoiesis Mettier and Rusk reviewed the literature and reported two cases The clinical course may be typically that of true leukemia, or the patient may have a leukemoid blood picture characterized by leukopenia and a hemorrhagic tendency Enlargement of the spleen may be found on physical examination

Examination of tissue removed from the marrow cavity reveals the presence of fibroblastic proliferation A few spicules of cancellous bone may be present The hemopoietic tissue is disrupted and in many areas is obliterated

MELORHEOSTOSIS —This is a rare abnormality of the bones The condition was first described by Leri and Joanny in 1922 The structural changes are represented by hyperostosis of the cortex of the bones There is excessive formation of a dense sclerotic bone which may be of endosteal or periosteal origin The changes are usually unilateral in distribution and affect the long bones Thirty-nine such cases have been reported in the literature Recently, Carpender and his associates reported two additional cases but claimed distinction in that one case showed a bilateral distribution

Attention may be attracted to the presence of such a lesion by localized soft tissue swelling or tenderness A patient recently examined by us complained of localized tenderness and swelling just above the knee which she believed was sustained from a slight blow There was localized swelling and deep tenderness without evidence of redness or bruising The roentgenograms revealed the changes characteristic of melorheostosis This is characterized by the sclerosis of the bones giving an appearance of flowing or dripping suggestive of the dripping of candle wax Roentgenograms of this condition once seen will leave a vivid impression

FIG 225 —Melorheo tosis

Blood chemistry reveals normal values for calcium phosphorus and phosphatase levels The etiology is unknown

MISCELLANEOUS DISEASES OF THE BONES

SPONDYLOLISTHESIS.—Spondylolisthesis is the term applied to the symptom complex resulting from forward subluxation of the fifth lumbar vertebra. This abnormality may result from some congenital anomaly or may be precipitated by trauma. Elongated transverse processes of the fifth lumbar vertebra may be an accompaniment. Pain is the outstanding symptom and may be described by the patient as a dull aching sensation low in the back. It may be relieved by rest. In cases of long-standing illness there is pain along the distribution of the sciatic nerve. Stiffness supervenes and restriction of forward bending frequently results. Marked lordosis may be present.

FIG. 226.—Spondylolisthesis.

The diagnosis is established on examining the roentgenogram. The lateral view may reveal the subluxation to best advantage.

SPINA BIFIDA.—This is a congenital anomaly due to failure of the neural arch to close. This varies in degree from a slight linear defect discernible in the roentgen film to a wide gape in the fifth lumbar and upper sacral vertebræ. When wide open there may be a sac like protrusion of the meninges (meningocele) that is rather serious in nature.

NEOPLASTIC DISEASES OF THE BONES

The sudden appearance of pain or swelling in the region of a bone not infrequently is the first sign of neoplastic degeneration. Benign and primary tumors usually can be diagnosed from the roentgenogram. Metastatic malignancies require careful clinical investigation in order to determine the primary source.

The classification of tumors of the bones recommended by the Bone Tumor Registry of the American College of Surgeons is shown in Table 65.

BONE CYST.—This is a solitary lesion which appears most frequently near the

MYELOFIBROSIS (*Fibrosis of the Bone-marrow—Myelosclerosis*) —This type of sclerosing process usually appears after the second decade The onset of illness is insidious and may be characterized by deep bone pain or tenderness The patient may consult his physician because of some symptom referable to an abnormality in hematopoiesis Mettier and Rusk reviewed the literature and reported two cases The clinical course may be typically that of true leukemia, or the patient may have a leukemoid blood picture characterized by leukopenia and a hemorrhagic tendency En largement of the spleen may be found on physical examination

Examination of tissue removed from the marrow cavity reveals the presence of fibroblastic proliferation A few spicules of cancellous bone may be present The hemopoietic tissue is disrupted and in many areas is obliterated

MELORHEOSTOSIS —This is a rare abnormality of the bones The condition was first described by Leri and Joanny in 1922 The structural changes are represented by hyperostosis of the cortex of the bones There is excessive formation of a dense sclerotic bone which may be of endosteal of periosteal origin The changes are usually unilateral in distribution and affect the long bones Thirty nine such cases have been reported in the literature Recently Carpender and his associates reported two additinal cases but claimed distinction in that one case showed a bilateral distribution

Attention may be attracted to the presence of such a lesion by localized soft tissue swelling or tenderness A patient recently examined by us complained of localized tenderness and swelling just above the knee which she believed was sustained from a slight blow There was localized swelling and deep tenderness without evidence of redness or bruising The roentgenograms revealed the changes characteristic of melorheostosis This is characterized by the sclerosis of the bones giving an appearance of flowing or dripping suggestive of the dripping of candle wax Roentgenograms of this condition once seen will leave a vivid impression

FIG 225 —Melorheostosis

Blood chemistry reveals normal values for calcium phosphorus and phosphatase levels The etiology is unknown

### Miscellaneous Diseases of the Bones

Spondylolisthesis.—Spondylolisthesis is the term applied to the symptom complex resulting from forward subluxation of the fifth lumbar vertebra. This abnormality may result from some congenital anomaly or may be precipitated by trauma. Elongated transverse processes of the fifth lumbar vertebra may be an accompaniment. Pain is the outstanding symptom and may be described by the patient as a dull aching sensation low in the back. It may be relieved by rest. In cases of long standing illness there is pain along the distribution of the sciatic nerve. Stiffness supervenes and restriction of forward bending frequently results. Marked lordosis may be present.

Fig. 296.—Spondylolisthesis.

The diagnosis is established on examining the roentgenogram. The lateral view may reveal the subluxation to best advantage.

Spina Bifida.—This is a congenital anomaly due to failure of the neural arch to close. This varies in degree from a slight linear defect discernible in the roentgen film to a wide gape in the fifth lumbar and upper sacral vertebræ. When wide open there may be a sac like protrusion of the meninges (meningocele) that is rather serious in nature.

### Neoplastic Diseases of the Bones

The sudden appearance of pain or swelling in the region of a bone not infrequently is the first sign of neoplastic degeneration. Benign and primary tumors usually can be diagnosed from the roentgenogram. Metastatic malignancies require careful clinical investigation in order to determine the primary source.

The classification of tumors of the bones recommended by the Bone Tumor Registry of the American College of Surgeons is shown in Table 65.

Bone Cyst.—This is a solitary lesion which appears most frequently near the

proximal end of the shaft of the long bones. It is usually found in persons under twenty years of age. The humerus is a frequent site for this formation which is found, incidentally, on roentgen ray examination of the skeleton. Pain or swelling is seldom present. Due to the expansion of the lesion there is pressure atrophy of the cortex of the bone, and as a result, pathologic fracture may occur.

The roentgenogram reveals the presence of a smooth, symmetrically expanded new growth within the medullary cavity. There

Trauma appears to be a precipitating factor. The lesion develops rapidly and a globular swelling can be felt; pain becomes the outstanding symptom. Geschickter and Copeland are of the opinion that the giant cell tumors are of subperiosteal origin. The osteoclasts proliferate as a result of an injury.

The roentgen manifestations are those of a solitary tumor mass that has expanded and caused pressure atrophy of adjacent bone. The mass appears somewhat translucent and trabeculated.

TABLE 65.—REVISED CLASSIFICATION OF BONE TUMORS (1939)

| | Malignant | Benign |
|---|---|---|
| I Osteogenic series—*osteogenic sarcoma* | 1 Medullary and subperiosteal | 1 Exostosis |
| | 2 Telangiectatic | 2 Osteoma |
| | 3 Sclerosing | |
| | 4 *Periosteal* | |
| | 5 Fibrosarcoma | |
| | (a) Medullary | |
| | (b) *Periosteal* | |
| | 6 Parosteal capsular | |
| II Chondroma series | 1 Chondrosarcoma | 1 Chondroma |
| | 2 Myxosarcoma | |
| III Giant cell tumor series | 1 Malignant | 1 Epiphyseal giant cell tumor |
| IV Angioma series | 1 *Angio-endothelioma* | 1 *Cavernous angioma* |
| | 2 Diffuse endothelioma | 2 Plexiform angioma |
| V Myeloma series | 1 Plasma cell | |
| | 2 Myelocytoma | |
| | 3 Erythroblastoma | |

| VI Reticulum cell lymphosarcoma | | |
| VII Liposarcoma | | |

is no evidence of penetration into the osseous tissue.

Treatment is usually surgical and not necessarily indicated unless pain is marked or spontaneous fracture occurs.

BENIGN GIANT CELL TUMOR.—Benign giant cell tumor of the bone is a solitary lesion. It usually appears after the second or third decade. The lesion is most frequently located just above or below the knee. It has been reported in the radius but is of less frequent occurrence in the bones of the skull. The lesions are usually in the long bones at or near the epiphyses where cartilage is undergoing osteogenesis.

The diagnosis can be established on biopsy of the tumor. The tissue appears hemorrhagic and is friable. The histologic findings consist of the presence of large numbers of multinucleated giant cells without much evidence of fibroplastic proliferation.

Benign giant cell tumors usually respond well to treatment with roentgen ray irradiation.

Benign giant-cell tumor is to be distinguished from eosinophilic granuloma of bone (See Chapter 26).

OSTEOLYTIC SARCOMA (*Sclerosing Type*).—This is a highly differentiated type of bone sarcoma. It is most often found in young persons between fifteen and twenty-

five years of age The tumor is made up of large numbers of osteoblasts The lesion is essentially a proliferative one and according to Geshickter and Copeland osteogenesis may arise from intracartilaginous or membrane tissue There is an admixture of osteoid tissue with actual spicules of bone fine spicules of bone Metastases of the tumor to the lungs may occur by the bloodstream

In the roentgenograms the abnormal tissue appears as dense, irregular areas of newly formed bone radiating from within the shaft of the bone out into the soft tissue

FIG 227—Giant cell tumor of the lower end of the femur in a young girl aged twenty two years (Comroe s Arthritis)

There is local extension of the process through the cortex of the bone and into the regional soft tissues On clinical examination soft tissue swelling is usually *apparent and there* may or may not be tenderness on pressure Crepitus may be felt on palpation due to the presence of

The treatment consists of amputation of the affected limb if there is no clinical evidence of metastases

OSTEOLYTIC SARCOMA (*Osteolytic Form*) — Clinically this type of sarcoma is differentiated from the sclerosing type with considerable difficulty It is a highly *de*

proximal end of the shaft of the long bones It is usually found in persons under twenty years of age The humerus is a frequent site for this formation which is found incidentally, on roentgen ray examination of the skeleton Pain or swelling is seldom present Due to the expansion of the lesion there is pressure atrophy of the cortex of the bone, and as a result, pathologic fracture may occur

The roentgenogram reveals the presence of a smooth symmetrically expanded new growth within the medullary cavity There is no evidence of penetration into the osseous tissue

Treatment is usually surgical and not necessarily indicated unless pain is marked or spontaneous fracture occurs

Benign Giant Cell Tumor —Benign giant cell tumor of the bone is a solitary lesion It usually appears after the second or third decade The lesion is most frequently located just above or below the knee It has been reported in the radius but is of less frequent occurrence in the bones of the skull The lesions are usually in the long bones at or near the epiphyses where cartilage is undergoing osteogenesis

Trauma appears to be a precipitating factor The lesion develops rapidly and a globular swelling can be felt pain becomes the outstanding symptom Geschickter and Copeland are of the opinion that the giant cell tumors are of subperiosteal origin The osteoclasts proliferate as a result of an injury

The roentgen manifestations are those of a solitary tumor mass that has expanded and caused pressure atrophy of adjacent bone The mass appears somewhat translucent and trabeculated

Table 65 —Revised Classification of Bone Tumors (1939)

| | *Malignant* | *Benign* |
|---|---|---|
| I Osteogenic series—osteogenic sarcoma | 1 Medullary and subperiosteal | 1 Exostosis |
| | 2 Telangiectatic | 2 Osteoma |
| | 3 Sclerosing | |
| | 4 Periosteal | |
| | 5 Fibrosarcoma | |
| | (a) Medullary | |
| | (b) Periosteal | |
| | 6 Parosteal capsular | |
| II Chondroma series | 1 Chondrosarcoma | 1 Chondroma |
| | 2 Myxosarcoma | |
| III Giant cell tumor series | 1 Malignant | 1 Epiphyseal giant cell tumor |
| IV Angioma series | 1 Angio-endothelioma | 1 Cavernous angioma |
| | 2 Diffuse endothelioma | 2 Plexiform angioma |
| V Myeloma series | 1 Plasma cell | |
| | 2 Myelocytoma | |
| | 3 Erythroblastoma | |
| | 4 Lymphocytoma | |
| VI Reticulum cell lymphosarcoma | | |
| VII Liposarcoma | | |

The diagnosis can be established on biopsy of the tumor The tissue appears hemorrhagic and is friable The histologic findings consist of the presence of large numbers of multinucleated giant cells without much evidence of fibroplastic proliferation

Benign giant cell tumors usually respond well to treatment with roentgen ray irradiation

Benign giant-cell tumor is to be distinguished from eosinophilic granuloma of bone (See Chapter 26)

Osteolytic Sarcoma (*Sclerosing Type*) — This is a highly differentiated type of bone sarcoma It is most often found in young persons between fifteen and twenty

and lymph nodes. A fatal termination of the illness usually occurs after a period of a few months to one or two years.

MULTIPLE MYELOMA (*Plasmacytoma, Plasma Cell Myeloma*).—This highly malignant disease of the bones, in the experience of the writer from observing cases on the wards of the University of California Hospital, may be of more frequent occurrence than is generally supposed. As the name implies, multiple tumors are present throughout the skeletal system. (For further discussion of this disease *see* Chapter 25.)

METASTATIC MALIGNANCY.—Metastatic malignancies to the bone show certain characteristics in the roentgen films which permit recognition of two types of reaction. The one most frequently observed is osteolytic (bone destroying) in character and the other is osteoblastic (bone forming). The metastatic lesions stimulating osteolytic activity are recognized by decalcification and destruction of bone. In the osteoblastic metastases there is increased calcification and the tendency to new bone formation around carcinomatous processes.

Carcinoma of the breast, according to most authors, is one of the primary tumors that metastasizes most frequently to the bones. The medullary cavities or osseous tissue of the vertebrae, the pelvis, the femur and the skull are the regions likely to be invaded. In the roentgenograms the metastatic lesions are seen as irregularly outlined translucent areas of varying size. Some may be surrounded by merely a thin shell of bone. Such foci are usually multiple.

In most cases of bone metastasis a primary carcinoma of the breast has been recognized clinically and the phenomenon of dissemination occurs during the course of illness. In our experience, however, the clinical recognition of such metastases have occurred as late as eleven years after the removal of a breast for carcinomatous degeneration. On the other hand, a metastatic focus may be found in a patient who is entirely unaware of a tumor nodule in the breast.

Lesions of metastatic carcinoma of the bone that are essentially osteolytic in nature may come from primary sources other than the breast. Hypernephroma, carcinoma of the thyroid, bronchogenic carcinoma, neuroblastoma and carcinoma of the rectum not uncommonly disseminate through the blood stream to the bones.

Carcinoma metastases stimulating osteoblastic activity are limited almost entirely to those arising primarily from the prostate. In the roentgenograms these lesions are recognized by varying sized translucent foci surrounded by an increased density of the bone. The pelvis, vertebrae, upper end of the femur and the skull may show such lesions.

Clinically, pain is the most outstanding symptom which may call attention to a focus of carcinomatous metastasis. At first it may be dull, aching and intermittent in character, becoming constant and agonizing later. In contrast to this there may be an abrupt onset of excruciating pain accompanied by disability. A metastatic nodule may be suspected in the region of the pain if there is spasm of the regional muscles, slight pitting edema and deep bone tenderness.

It is not uncommon to find an altered blood picture during the course of illness. There is usually a normochromic or normocytic type of anemia. There may be a leukopenia or leukocytosis. Normoblasts and myelocytes may be observed in the blood films.

In patients with carcinoma of the breast metastasizing to the bones there may be slight elevation of the serum calcium, phosphorus and phosphatase levels. Gutman and Gutman have shown that the acid phosphatase level of the blood serum is definitely increased in metastatic cancer of the prostate to the bones. In the early reports it was believed that the amount of cancer metastasis could be correlated with the amount of acid phosphatase in the serum. Recent studies, however, are not entirely in agreement.

Roentgen ray irradiation of the bones has been the method of choice in the treatment of carcinomatous metastases. Relief of pain may come to some patients, whereas this method of treatment may only aggravate the symptoms of others. The method is only palliative.

In some of the recent experimental work it is suggested that estrogenic substances may play a role in the rate of growth of

structive growth extending through the shaft and cortex of the bone without much tendency to invade the surrounding tissues Due to the extension of the lesion within the bone and its resultant decalcification the tumors are soft and fluctuant There is increased vascularity within its structure—the vascular engorgement of which has been referred to as 'bone aneurysm The tissue on microscopic examination is found comprised of osteoblasts among which are many mitotic figures Intermingling within these or closely associated with them are large, malignant-appearing spindle cells

In the roentgenograms there is evidence of much destruction of bone Almost the entire circumference of the shaft of the bone may be replaced by a translucent new growth There may be some evidence of osteoblastic proliferation and the formation of spicules of bone but not to the extent that is characteristic of the sclerosing type of growth

Chondromas —Chondromas are localized overgrowths of cartilage that may appear in any region where there is cartilage Ewing states that there is a tendency for these structures to reproduce normal types of cartilage Ossification of these benign tumors may occur

Chondrosarcoma —Primary chondrosarcomata involving the bones is comparatively rare It is of a highly malignant nature, occurring at about the age of puberty

Ewing's Tumor (*Ewing's Sarcoma Ewing's Endothelial Myeloma Myelo-endothelioma*) —Ewing's sarcoma is a comparatively rare form of bone tumor appearing in the second and third decades of life Men more frequently are affected than women The etiology of this condition is obscure but trauma is thought to be a contributing factor The primary site may be the middle of the shafts of the long bones but metastases may go to the flat bones Pain is the outstanding symptom and may be more severe at night It is usually described as dull and aching in character with periods of remission and exacerbation Early in the course of illness a swelling is sometimes to be found on examination As the disease progresses a large fusiform swelling appears which may extend the entire length of the bone

There has been considerable difference of opinion concerning the origin of this tumor The cells comprising the tumor are small round cells which possibly arise from the lymphatic channels Ewing considers the tumor as non osteogenic in origin and classifies it as an endothelial myeloma

Fig 228 —Ewing's sarcoma in middle third of humerus

Pancoast states the bones present no characteristic roentgen appearance in Ewing's tumor The onion peel osteoblastic reaction often referred to may also be found in other lesions

The tumor cells are sensitive to the roentgen ray and following a course of treatment the swelling may subside Recurrences of the local lesion are prone to occur Metastases have been reported to the lungs skull

# PART VI
# CARE OF AGED AND REHABILITATION

## Chapter 29

# The Care of the Aged

By RICHARD A. KERN, M.D.

*Gerontology* is a study of all aspects of old age: the processes of aging, the retardation of those processes and the minimizing of their effects, the manifold problems that accompany old age, the ways in which those problems can best be solved.

*Geriatrics* deals only with the medical aspects of gerontology.

The importance of nonmedical factors in the causation of a disease and in the management of the person with that disease receives daily emphasis in medical practice. The physician knows, and the student must learn, that such matters as the social environment and the economic status of the patient must be considered in solving the medical problems of his patient. But in general the textbook of medicine gives scant notice to such nonmedical factors, chiefly because of limitations of space and partly because of their discussion in other texts.

An exception to this usage must be made in presenting this chapter on the care of the aged. There are several reasons why the nonmedical aspects of gerontology must here be stated in some detail. The problems posed by the aged in such fields as economics, politics, philosophy, religion and medicine have assumed formidable proportions only within the present generation. Moreover, they are increasing at a rate that will double their importance within decades as compared with centuries in the past. There are as yet no ready solutions for many of these problems, since they have become pressing only very recently and so have attracted little thought or attention heretofore. It is therefore the more important to state the problems in order to enlist new workers in their study.

*Increase in Average Longevity.*—The average length of life in Rome in Cicero's time was 23 years. In England about the year 1000 it was 35 years. (In India today it is still only 27 years.) In the United States in 1900 it was 47 years, an increase of only 24 years in nearly 2 thousand years. But in 1948 our figure stood at 67 years, and it will reach 70 in the early 1950's.

*Increase in Percentage of Aged in the Population.*—In 1850 only 2.6 per cent of the people of the United States had reached the age of 65. In 1950 those over 65 constitute about 8 per cent of the population and, according to the actuarians, will constitute 14.5 per cent by 1980. These are average figures; higher percentages obtain in certain areas (West Coast, New England) and in urban populations. The 1940 census listed as over age 65 some 8.2 per cent in San Francisco, 8.3 per cent in Los Angeles, 8.7 per cent in Oakland, 8.7 per cent in Seattle and 9.5 per cent in Portland, Oregon. The aged are forcing themselves on our attention by the sheer weight of their numbers.

The chief reasons for the longer average life are decreased infant mortality and the

cancer of the breast and prostate It has long been known that castration of a man with carcinoma of the prostate will inhibit the growth of metastatic foci in the bones Huggins recently reopened the subject and reported that following castration a considerable number of his patients remained symptom free for over thirty months Dean, Twombly and Woodward report the results of their work on chemical castration produced by the administration of stilbestrol The outcome closely parallels that of castration produced through surgical measures

In regard to carcinoma of the breast Taylor has shown that the injection of female hormone (estrogen) in mice of high cancer incidence will stimulate alteration of breast tissue Dresser has shown that temporary regression of extensive metastasizing cancer of the breast in women while still in the menstruating age may be induced by irradiation of the ovaries A great deal of interest has arisen regarding the favorable effects of testosterone on the course of mammary cancer Symptomatic relief and quiescence of osseous metastases have been reported in certain patients However the results have so far been unpredictable and transient The Therapeutic Trials Committee of the Council of Pharmacy and Chemistry of the American Medical Association is conducting an intensive investigation of this problem At present no definite conclusions can be drawn

## Chemical Poisons

**Fluorine Poisoning** —Absorption of fluorine is an industrial hazard encountered by workers in rock having a high fluorine content Fluorine poisoning may also result from the ingestion of sodium fluoride contained in roach powders Changes occur in the bones characterized by increased density and a tendency toward brittleness

**Radium Poisoning** —Radium poisoning has been an industrial hazard resulting from the ingestion of soluble radium salts over a long period of time The use of radium in the manufacture of luminous watch dials has been stopped through legal measures Precautionary measures against exposure to radioactive substances are being instituted in medical laboratories and industries where this material is used Cases of radium poisoning are therefore becoming of rare occurrence The bone changes consist of extensive areas of necrosis and absorption of osseous tissue There is a tendency toward pathologic fractures The course of illness may run a period of years The patient eventually succumbs to an aplastic type of anemia

*State old-age pensions* vary widely in amounts depending on the economic resources of the individual states. In 1948 such pensions ranged from a low of $18.79 a month in Mississippi to a high of $70.63 a month in California. Pennsylvania paid $40.12 a month. If these figures are compared with the basic cost of living per couple per month at that time—$125 to $152, depending on the state—it is clear that such old-age pensions fall short of providing even the barest subsistence in most instances. To the suggestion "why not higher pensions?" the obvious answer is: it would be very expensive. If all the aged were eligible for a $75 pension at age 63, the cost for the nation as of 1948 would have been 11.7 billions of dollars. Exactly that pension was voted in California in November 1948, but a year later, when the financial resources of that state seemed seriously threatened, the plan was modified by raising the pensionable age to 65. In 1949 California had 245,295 persons on old-age pensions, nearly 3 times as many as Pennsylvania with about the same total population.

State old-age pension plans, as well as social-security programs, are open to one important criticism: they are not based on sound actuarial principles. They are all on a "pay-as-you-go" basis, that is, benefits come out of current tax income rather than out of financial reserves. When times are good, tax income is high and potential beneficiaries are relatively few, the plans seem secure enough. But what will happen when times are less prosperous, tax income is lower or has been diverted to other more pressing expenditures, and potential beneficiaries have greatly increased?

4. *By Private Pension Plans.*—An increasingly important source of subsistence funds for the aged is developing in nongovernmental pension plans. Their rapid growth is evident from these figures: In 1941 only 600,000 persons in the United States had such coverage. By early 1949 their number had risen to 6,500,000, and the 9 million mark will have been reached during 1950. A significant fact is the adequacy of the pensions involved. Of those in force in 1949 only 25 per cent were for less than $100 a month, 55 per cent were for $100 to $125, and 20 per cent for over $125.

These private pension plans are of 2 chief types: *individual pension insurance* for premiums paid to an insurance company by the persons insured, and *industrial pension insurance*, in which the employer guarantees to the employee certain pension rights ("deferred wages"), often with payment participation by the employee out of wages, and variously administered as to cash reserves, re-insurance and supervision. Both types are on an actuarial basis.

But there are certain weaknesses in many industrial plans. In periods of depression not necessarily of a general nature but in a particular industry or in a given company (*e.g.*, when new inventions make an older product obsolete) there may be difficulty in meeting pension payments unless there are strong cash reserves. Yet it may be difficult to set up adequate cash reserves, especially at the time of installation of a pension plan. Only the strongest and largest organizations could escape bankruptcy under certain adverse conditions. In the longest strike in the automobile industry (Chrysler Corporation, 1950) the chief issue was not wages but the pension plan—the size of the proposed cash reserves and participation in administering the plan.

The actuaries are having increasing trouble in evolving sound pension plans. When mortality statistics shift in the direction of longer life, the life-insurance companies benefit but pension plans suffer. A pension contract is a promise to pay back to an individual money saved in premiums during working years, the payments to continue from a stated age until death. To be sound, the contract must be based on the ability to predict with reasonable accuracy the life expectancy of the average individual. The mortality statistics of a country are the basis for such predictions. The difficulties that unforeseen and marked changes in mortality data place in the way of the predictors are obvious.

There is another ghost at every pension feast. Pensions are essentially savings. What will the dollars saved today buy some decades hence? To say that every worker by the year 2000 will have an annual income

better prevention and treatment of infections at all ages Other medical triumphs could also be cited In the United States, a lowered birth rate and diminished immigration have served to increase the percentage of aged in the population

## ECONOMIC PROBLEMS

Of major and rapidly increasing concern are the economic problems which an aging population is creating in this country

Thrift is not a common virtue Of those over 65 only 5 per cent have saved a sufficient competency to be self supporting The rest must work or depend upon others for their maintenance But only 25 per cent of these oldsters are gainfully employed Therefore, 7 out of every 10 of those over 65 are now being supported by others Those over 65 today constitute 11 per cent of those over 18 that is 1 oldster for every 8 younger workers In 1980 they will constitute 20 per cent of those over 18 or 1 oldster for every 4 younger workers The speed with which this trend toward more aged in the population is moving can be judged from these figures between 1930 and 1940 our total population increased 7 per cent but the number of those over 65 increased 35 per cent It is clear that more and more old people must be kept by relatively fewer and fewer young people

*The basic economic needs* of all persons can be grouped under 3 headings *Subsistence* (food shelter clothing and the like) *care* (simple help from others for those unable to help themselves children the injured crippled and infirm) and *treatment* (the costs incident to illness) The aged differ from the rest of the population chiefly in their proportionately greater need for *care* and *treatment*

It is instructive to examine the ways in which these basic economic needs of the aged have been met in the past and are being met today

SUBSISTENCE —1 *By Working or Through Their Own Savings* —This is the ideal solution The sweetest bread is that which we earn by our own efforts, the bitterest, the bread of charity It is the happiest solution because it assures the oldsters of the independence of living in their own quarters No house is big enough to hold two families

2 *By the Help of Children* —The Fourth Commandment has solved the problems of the great majority of our aged in the past Let it be said that the help of children is best applied by maintaining the parents in their own homes The homes of the children are a second best choice the parents are at least not among strangers, even though they are less independent

But this solution is less available than formerly, when there were large families and big homes Today there are fewer children, and there is no room for a parent in the modern small house or apartment During 8 recent years the writer helped process about 2000 applications for admission to a large home for the aged No less than 95 per cent of the applicants had no living children As for the rest their children were either too old themselves or for various reasons unable rarely unwilling to help their parents

3 *By State Aid* —More and more government has had to step in with financial help when other sources were not available Funds have been provided by means of enforced savings and through taxation notably in the form of *social security benefits* and *old age pensions*

(Again such funds are best applied to maintain the aged in their own homes Second best are living quarters with children or friends Another type of home establishment that is increasing in numbers is the *pseudo-family* when two or more unrelated oldsters pool their resources to provide themselves with a house or apartment The problem of housing is further complicated by the widowed state of the old person it is more economical to shelter two than one in a room Yet in 1940 of men over 60 20 per cent were widowers and 10 per cent were single or 30 per cent alone Women over 60 were 44 7 per cent widows and 9 3 per cent single or 54 per cent alone )

*Social security benefits* are being increased in amounts and in groups covered Commendable though this method of support for the aged is it has a weakness to be mentioned later

of the patients now in general hospitals in Philadelphia could be cared for in their own homes if certain services were there provided by the hospitals and professional groups housekeeping help, nursing medical attention such gadgets as wheel-chairs and hospital beds laboratory service, and physiotherapy The efforts along these lines being made by certain hospitals (the Montefiore Hospital in New York the Germantown-Chestnut Hill Hospitals and Children s Heart Hospital in Philadelphia) are being watched with interest In Philadelphia the Purple Cross is an organization of registered nurses who pledge themselves each to give one day a year of free nursing service to patients at home

*The cost of treatment* can be listed under 3 headings (1) *the cost of hospitals*, (2) *the cost of hospitalization* and (3) *the cost of physicians services* The first is borne by the public the last two by the patient

The *cost of hospitals* is a complex responsibility in our economy The earlier hospitals were privately built by charitable citizens Then communities at the local level provided additional hospitals Increasing costs and unequal resources in different parts of the country brought State and Federal aid into the picture There is still a major local responsibility for the cost of hospital construction The chief governmental source of funds for this purpose is through the provision of the Hill Burton Act

An important factor in the wise expenditure of money for building new or enlarging old hospitals is the establishment of *voluntary local planning agencies* to assess local needs for and efficient use of hospital beds Such planning is as yet only in its beginnings

The *cost of hospitalization* and the *cost of physicians services* are seldom considered separately in current discussions of how the individual is to be protected against the financial stress of catastrophic illness Yet they should be for most laymen are under the impression that physicians services are largely responsible for the high cost of major illnesses and so are easily swayed to align themselves against the medical profession in considering solutions for meeting the high cost of medical care Actually the cost of physicians services are only a small fraction of the total cost of the major illness that puts a patient into a hospital

It is clear that protection of the individual against the cost of catastrophic illness can be achieved just as against any other major loss only by insurance The chief question at issue in this field today is whether this may best be accomplished by voluntary plans or by compulsion through government This in turn, raises far reaching questions not only in economics, but in the political structure and philosophy of our nation Shall we sacrifice our democratic government by shifting to state socialism? That would be the probable result of a program that begins with compulsory health insurance The events in Great Britain point that way

This all seems far from the subject of the Care of the Aged yet their increasing numbers more than any other cause have been responsible for the raising of these serious and vexing economic and social questions It is clear that there is today no single panacea for the financial problems of the aged We must study and try out various plans and approaches we must figure their costs and how and by whom those costs can be met we must remember that the costs must be kept within our means to pay

Here attention is called to a basic economic principle the standard of living of a nation depends upon the total production of its people If more and more old persons must be supported by fewer and fewer workers then a lower standard of living will result We can avoid a lower standard of living in only 2 ways increased productivity of the workers or keeping more old people at work

A major medical as well as economic problem today is how to keep more old people gainfully employed Enforced retirement is certainly not a generally desirable principle in industry There should be elastic rules to keep those in good health and physical condition at work beyond a stated age

Here industry must rise to the occasion with new programs The oldster should keep on working but not necessarily at the same job There is need for new employee groups to which only older workers are

of $5000 is meaningless if the purchasing power of that dollar is not defined Every adult today has had enough experience to know that the net result of changes in money value in the long run is inflation, not deflation

It should be clear that pensions alone can not be expected to solve all the financial problems of the aged

CARE —When an individual needs personal help in addition to basic subsistence, his economic situation becomes much more difficult *Care* costs about two and a half *times as much as does bare subsistence* when that care has to be furnished by a stranger to a single person The prolonged cost of a practical nurse for example, is beyond the means of many individuals or families and beyond all or most pensions *Care* is low in cost only (*a*) when given free by the members of the family or (*b*) when administered to large groups of needy in an institution

1 *Homes Government supported* —Government, usually at the local level (city or county), has therefore had to provide through taxation such institutions for the indigent who need care in addition to subsistence However the standard of living which obtains in such "homes" is at the lowest possible level of existence the tax payers see to that Moreover those who enter can not pick their company The *chief objection to these institutions is that* there is only one criterion for admission indigence These facts all too often combine to justify *the name that such places have* carried through the years "Poor House"

2 *Homes Privately Supported* —There will always be a need and a *place* for the "Home for the Aged" as provided by particular groups in the community a religious body a racial group, a lodge a trades union a profession, and for obvious reasons There is a personal interest on the part of the benefactors who take pride and satisfaction in their undertaking The beneficiaries find themselves in congenial surroundings among people some of whom they knew before and all of whom share common interests and a common background As a result of these facts and in spite of rising social benefits at the hands of government, there has been no reduction but a steady increase of petitions for entry into such homes of the aged in sharp contrast to the decreasing numbers of children in orphanages

TREATMENT —When illness enters the picture there is the sharpest upswing in the cost of an individual s needs The aged are victims *far out of proportion to the rest of the population In 1940 among* policy holders of the Metropolitan Life *Insurance Company the average number of* days of incapacitating illness was 6 9 a year but those over 65 were ill 35 days a year *In* a large home for the aged known to the writer, a home whose inmates have an average age of 79, the average number of days in hospital for each inmate is 91 a year

1 *Hospitals* —Little wonder then, that elderly patients today fill a majority of the beds in all our general hospitals But general hospitals are intended primarily for the acutely ill and are provided with every diagnostic and therapeutic facility this makes for the highest cost of daily maintenance It is therefore financially unsound to use such beds for those with chronic illness requiring little beyond nursing care

There is consequently a growing and pressing need for special hospitals for certain types of cases hospitals for the mentally ill, *for paralytics* for arthritics for cardiac patients and for the blind

There is particular need for a new type of *hospital facility for the aged* a glorified infirmary that would meet the nursing and simpler medical needs of its inmates but *would be close enough to a general* hospital to be served by the latter s special facilities and staff In a small community this might *be a floor or a wing of a general hospital in larger communities* a separate building in the immediate vicinity of a general hospi*tal would be better*

But it will take time and money to provide such new buildings for the care of our aged *patients The financial problems* of our general hospitals are so urgent today that earlier and cheaper solutions are being sought by *hospital administrators* Of particular promise is *the possibility of projecting hospital care into patients homes In a recent survey* the Philadelphia Health and Welfare Council found that 50 per cent

changes Bone loses some of its mineral content and appears less dense in roentgenograms Cartilage, especially over joint surfaces and in the intervertebral discs, becomes thinner so that loss in stature to as much as a couple of inches results Bad posture with increased stoop will exaggerate this loss in height

Atrophy of alveolar septa and stretching of inelastic alveolar walls are characteristic of the lungs of the aged

Liver spleen kidneys, and pancreas show increase in fibrous septa and varying degrees of atrophy of parenchymal tissues

The endocrine glands share in these changes and probably play an important role in the process of aging

The brain is longer spared than most tissues but later shows both atrophy and fibrosis Its sensory receptors however show constantly some characteristic changes and deterioration sclerosis in the inner and middle ear atrophic changes in sensory nerves Here can also be mentioned the diminishing elasticity of the crystalline lens

*Changes in Function* —There are alterations in function many of which are related to the structural changes above noted The diminished capillary bed of the skin is largely responsible for the lessened ability of the aged to stand the cold What is less generally appreciated but more important is that the same reason makes it hard for the aged to dissipate heat through the skin and so to stand hot weather It is the aged who are the first and most numerous victims of a heat wave The dryness of the skin makes it more vulnerable to the effects of soap and detergents

The blood pressure tends to rise in the less elastic arteries Diminished blood supply results in lessened function generally

In the lungs the lessened capillary alveolar area progressively limits gas interchange between blood and air and consequently limits the activity of the individual

Lack of teeth may impair nutrition both by altering the kind of food eaten and by making it less easily digestible Gastric achylia and therefore impaired digestion are common yet so frequently symptomless or so vaguely suggested as to be overlooked Constipation is common due in part to the atrophy of the smooth muscle of the intestines

Of great importance but as yet not well understood are functional changes in the endocrine glands Sexual function wanes and ceases the basal metabolic rate declines Many subtle chemical changes in all portions of the body develop in the wake of flagging pituitary function The changes in structure and function that take place gradually during aging may occur with dramatic speed in diseases in which pituitary failure plays a major role such as Simmonds disease seen oftenest in women at the menopause and progeria that disease in which the picture of advanced senility is seen in adolescents A fuller understanding of the role of the endocrines in nutrition and aging may furnish the means for influencing these processes and delaying senescence

Last to deteriorate is the mind Long after evidences of decadence are present in other bodily functions the mental activity continues if not unimpaired certainly at a high level of efficiency (Perhaps this is at least one reason why mentally no one believes himself to be old even though he is conscious of the physical limitations which aging has imposed upon him) Certain faculties wane sooner than others The ability to memorize is the first aspect of memory to lessen There is prolongation of reaction time before skills themselves are lost Impairment of vision is usual but hearing may be long preserved There is diminution of acuity and intensity of touch pain and temperature perception Tendon reflexes tend to diminish and may even disappear The pupillary reflex to light may show similar changes

There are *psychological changes* that are part of the picture of aging Here it is not easy to separate that which is normally to be expected from that which is produced by severe stresses be these incident to intercurrent diseases or to social or economic misfortunes The psychologic changes are also conditioned by the personality of the individual and his consequent ability to adjust himself to life situations Impatience and irritability are often born of the lack of understanding by others as well as the old-

eligible Jobs must be found in which these can work at a slower pace, for shorter hours, perhaps for less pay but needing less or no pension, above all being happier the while

Industry is becoming increasingly aware of the fact that the old worker has advantages that offset in variable measure his handicaps of less speed strength and endurance In his favor are experience judgment and stability Absenteeism for any reason save illness is far less in the older age groups

POLITICAL PROBLEMS — Those over 65 comprise 12 5 per cent of those over 21 the voters and in 1980 they will be 25 per cent So large a minority can decide elections

Therefore politicians are appealing to the aging voters to gain their own ends Promises are made some in good faith others evidently with no possible thought of fulfillment California found a 75 dollar pension at age 63 too expensive in 1949 yet in 1950 a gubernatorial candidate promised a 100 dollar pension Political economy is a well-known discipline, but there is no such thing as economical politics

A more sinister angle of the political problems is this the idea of the welfare state is easy to sell to the impecunious old and near old Politicians find here a means to power at the expense of democratic principles Bread and Circuses was the slogan of the Roman politicians 2000 years ago today it has been condensed to one word Security Let it be remembered that Hitler did not seize power but on the basis of promises of a better lot was voted into office in an honest election One by-product of the hand out state is reduced initiative in its citizens and a consequent lowered production that lowers the standard of living But the greatest tragedy of the welfare state is the piece meal destruction of personal freedom

PHILOSOPHICAL PROBLEMS — Some believe that the increasing proportion of aged in the population will lead to greater conservatism in outlook and action with less chance for error but also less advance This is open to question, since the aged are inclined to take chances and because they can consider impartially the long range plans beyond their own life span Perhaps the benign influence of the women will play an increasing role since they are living longer than the men their life expectancy at birth today is 69, as compared with 66½ for the male Thus in 1930 among those over 65 there were 118 women for every 100 men In 1940 this ratio had increased to 124 100

## MEDICAL PROBLEMS

What has thus far been said in this chapter has the purpose of bringing into proper focus and perspective the problems that face the physician in his care of the aged It is not just a matter of the prevention diagnosis and treatment of disease in an old person, nor the attempt merely to prolong life Much more is it the preservation of health and efficiency as long as possible The goal in the words of Stieglitz is to put more life into years not just more years into life

*What is Old Age?*—It may be adumbrated rather than defined as the inexorably accumulating sum of a series of deteriorative changes in structure and function subtle and minimal in their beginnings yet eventually so marked and obvious as to be universally known and recognizable

*Changes in Structure* —The commonest structural change that characterizes the process of aging is atrophy It occurs in practically every organ and tissue save only the heart which is usually late and last to show it With it frequently goes a replacement of more vital cells by fibrous tissue The more important anatomic changes are the following

The skin loses much of its capillary bed its fatty panniculus diminishes its hair loses pigment whitens falls out and its specially functioning structures (sweat and sebaceous glands hair follicles) are undernourished atrophy and may in part disappear At the last the skin is thin wrinkled dry pale and cool Mucous membranes have comparable changes with loss of teeth and with diminution in numbers of secretory glands

Blood vessels more especially the arteries become less elastic somewhat lengthened and even tortuous

Muscles atrophy generally not only skeletal muscle but also the smooth muscle of the digestive tract

Bone and cartilage show characteristic

as exemplified by racial or local groups with divergent records for longevity Deficiencies of vitamins or minerals may be as important in speeding senescence as in delaying growth There is accumulating evidence that atherosclerosis may be related to the ratio between cholesterol and lipids in the diet The availability of fluorine in childhood determines the durability of the teeth The possibilities for investigation experimental statistical and clinical of the relation of nutrition to aging are among the greatest in all contemporary medicine

Closely allied to and frequently inseparable from nutrition is the role of endocrine function in the processes of senescence Here too our knowledge is fragmentary and theoretical But chemistry is opening avenues that should lead to surer ground than have the cruder methods of the past

In the realm of the psyche, early influences have an important bearing on mental problems in the aged Personality is the combined product of heredity and of conditioning experiences in early life Therefore attention to mental hygiene in youth will pay dividends in better adjustment and greater happiness in old age

All through life there are stresses whose effects on tissue and function must be far-reaching Infection is at times the obvious cause of a dramatically premature aging in an organ or organs Less obvious but cumulative may be the effects of minor but repeated infectious insults Or conceivably there may be favorable effects from symbiotic organisms It is not too far a cry from Metchnikoff s theory of longevity as related to the intestinal flora to the role of fungi (*e g* penicillin) in the control of infectious diseases today

Heredity is the chief factor in determining the anticipated life span of an individual Thus far little is known of its mode of operation yet one may well hope that it too may be influenced more directly and immediately by chemical means (*e g* nutrition) Valuable as have proved the methods of breeding in modifying heredity in plants and animals their application in man eugenics has been minimal and the results negligible

## WHAT CAN BE DONE TO PROLONG LIFE?

One evening the writer sat next to a prominent surgeon, past 70 in years but so much younger in mind and body that he could have claimed the late fifties When asked his secret of perpetual youth, he answered 'That s easy Meet this gentleman my father he s 93 The importance of heredity in aging as well as in life expectancy is well shown by the observations of Kallmann and Sanders in 1 602 twins In the monozygotic (uniovular) twins there was a striking parallelism not only in the length of life of each of the pair but in the time and manner of aging in various organs and tissues, and in the cause of death Dizygotic twins varied as widely in all these points as did any non twin siblings Unfortunately we can do nothing as yet about heredity

Yet there is promise that someday something may be done to influence heredity If any one of a hundred bee larvæ is fed for only a few days in its early existence some 'royal jelly a substance produced in the throats of worker bees and extremely rich in pantothenic acid, the larva so fed will grow up to be a queen the rest will become workers A worker bee lives one year a queen bee five years Rats fed an omnivorous diet live longer than litter mates raised on a vegetarian regimen Rats also live longer if semistarved than if overfed Evidence is accruing that fat in the diet and hereditary weaknesses in metabolizing fats are related to atherosclerosis Therefore predictions are reasonable in promising a delay in vascular aging and a longer life span by controlling the cholesterol lipid ratio in the diet

Today the physician s efforts are primarily to be directed to help an individual to live out his expected life span efficiently and happily This involves not only the prevention and treatment of disease but instruction and guidance in a proper mode of life Naturally this mode of life must be cultivated in earlier years to achieve its results For descriptive purposes however it will here be called

*Hygiene for the Aging and the Aged* —The program of living best calculated to insure

ster s own physical limitations In any event old age brings with it a sobering influence on the psyche that may variously find expression as conservatism fatalism lessened enthusiasms and heightened pessimism

To practice medicine intelligently among the aging and aged, the physician must have a knowledge not only of the nature of the changes in structure, function and psyche that are incidental to aging but also of the order in which, and the time of life when those changes may be expected to appear His problem is comparable to that of the pediatrician who has had to work out a timetable of height weight structure-function intelligence factors in relation to age from birth to puberty

But the problem in geriatrics is much more complicated than that in pediatrics A major difficulty is to distinguish between that which is normal aging and that which is exaggerated and pathological change For example when is vascular change the disease arteriosclerosis rather than fibrosis in keeping with the individual s age? In general a helpful guide is to consider structural changes normal so long as they do not interfere with function for that age Then too, one must consider the hereditary background of the individual in deciding whether a given change in structure or function is timely or premature for that person

Especially in the realm of mind and psyche is it hard at times to distinguish between the normal and the abnormal Forgetfulness in little and recent things is an early and constant finding in senescence But it merges imperceptibly into pathological loss of memory An old patient of the writer s knowing that she might fail to tell or ask him about something at the time of his visit used to keep notes to compensate for the forgetfulness that her 80 years justified But eventually she could no longer remember what she had written on one side of the paper and so repeated her questions *on the other* side Pessimism and worry may be fully justified in the light of impending poverty loss of employment or illness But such emotions may be magnified out of all proportion into miserliness that causes an individual to starve when he has many thousands of dollars in the bank, or into a depression that leads even to suicide

Nor can one decide whether a given emotional reaction is normal or excessive without full knowledge of attendant circumstances It is easy to overlook *loneliness* as a justifiable cause of a psychological pattern A major trial in old age is the loss of one s spouse and contemporaries and therefore of one's confidants, companions and friends This is as true of the rich as of the poor and they can be more lonely and uncared for spiritually in the homes of their own children, with whom they live but whose lives they do not share than if they lived alone in a hall bedroom

The elderly all too often make matters worse in their environment by their own intransigeance Not realizing that they may be more of a liability than an asset in the household they fail to make any effort to offset this by being pleasant in manner or thoughtful in action As Thewlis has put it with brutal frankness the aged are often economically useless esthetically repulsive and temperamentally difficult In consequence there may be a hostility hidden or overt on the part of one or more members of the household against the oldster To loneliness is added discontent Suppressed emotions find expression in symptoms and complaints All this must be considered by the physician in assessing the psychological status of his patient

## THE MECHANISMS OF AGING

Although it would be naive to put the question What are the causes of old age? it is highly proper to inquire into *the mechanisms of aging* Just as there are many factors which are known to retard, alter or speed up the processes of growth and maturation so there must be many factors that similarly influence the processes of decadence at the other end of life Our *knowledge of them is as yet in its beginnings* and herein lies a fruitful field for research

Some leads are now apparent Nutrition covers a most important group of clues These include deficiency factors and diet composition not only over the years but especially at critical period in early life or

should they be multiple rather than a single vacation annually Except for the hottest part of the year it matters little in which season the holiday is taken

*Diversion* —An indispensable ingredient in the formula of growing old happily is the possession of a wealth of inner and spiritual resources with which to occupy the increasing hours of leisure Diversion unfortunately is today too often considered synonymous with amusement and amusement is becoming increasingly of the passive variety Radio television and reading of the newspaper — of the comic strip variety — are robbing us of our capacity for active diversions Yet it is far more soul satisfying to make music than to listen to it to draw a picture or model a figure, or even to whittle on a stick to study some new subject or read a thought provoking book article or editorial or to argue a timely topic with a friend all this for at least a part of the time rather than to sit idly while others act feel and even think for us

But to do such things in our old age and especially to do them well we must learn how to do them when we are young Old age is something that everyone expects to attain Moreover most persons now being born will do so Therefore education and training in youth certainly as early as the high school level should include this aspect of preparation for life

The most valuable education is one which not only teaches an individual how to think and study but how to continue self-education by self imposed disciplines after formal education ends That goal is rarely achieved even at collegiate educational levels today Yet in such self instruction lies a great source of happiness and satisfaction in the ever broadening mental horizon which it can bring throughout life, even when physical infirmity builds its increasing limitations

Therefore it is significant that public school systems are beginning to experiment in adult education by evening classes in the school buildings They are offering a wide range of subjects but with emphasis on cultural topics and the art of living Herein lies real promise for education is a never-ending process not something that like growth must stop with most people in their teens In fact there should be better results with adult students than are achieved in our schools and colleges with teen-agers We have proof of this in the records of G I students as compared with those of their less mature classmates

A major tragedy in old age is the progressive loss of one s contemporaries This must be compensated for as well as may be by regularly making new and younger friends, lest loneliness become overwhelming The youngest old people are those who preserve a fresh outlook on life by cultivating contacts with the young

Diversion then in old age depends in large measure on the inner resources that have been accumulated by the individual in his earlier years The greater those resources, the less is he dependent on others for diversion But much can be done to plan group activities for the aged Such programs are now being tried at community levels as a welfare activity with a full time staff to organize groups under volunteer leaders in clubs churches neighborhood centers to participate in entertainment social gatherings lectures musicales games and handicraft An important benefit is the opportunity to make new friends A fertile field for trying out such group activities is furnished by the homes for the aged that now shelter over half a million persons The chief lack here as the writer has found is of trained social workers who have had experience in working with groups of the aged

It must be emphasized that to work to best advantage and to enjoy diversion to the fullest the aged must be provided with proper glasses hearing aids and dentures This seems obvious but the aged are all too often unable to provide these for themselves and hesitate to ask others to do so It is the responsibility of children and other relatives to make such provision and it is up to the physician to remind them of this responsibility

*Moderation* must constantly be stressed in advising both the aged and those who look after them Moderation applies not only to work rest and diversion but also to diet habits and personal hygiene

evenness as well as slowness in the progression of aging consists of work, rest and diversion, in proper balance and governed by the watchword of moderation in all things

*Work* is a prime means to preserve vigor The wheel which doesn't turn, rusts An old Navy regulation in the case of ships out of commission called for jacking over the main engines one and a quarter turns every 24 hours Faculties and skills as well as muscles that are not used weaken and atrophy Therefore work calls for some physical and mental exercise, as well as exertion in as many activities as the individual can reasonably engage in as often as feasible

But work is more than a means of keeping body and mind vigorous It is the most important key to happiness A major step in the transition from immaturity to maturity is the realization that work in itself is enjoyment By the same token, continued happiness in old age is assured as long as there is work to do and enjoy Work is the best thing to give life an enduring purpose Without purpose life is not only futile, but becomes a burden Therefore work must be a part of daily life as close to its end as may be

The problem of finding work of a type that the oldster can perform has medical as well as economic aspects In our hospitals we see all too often the wrecks that result when a person persists in an occupation that is beyond his waning capabilities Necessity may have been the driving motive, but proper advice by a family physician might have convinced him of the value of half a loaf We learned in war time that even old automobiles lasted many years as long as they were driven at moderate speeds but broke down promptly after the war when speed restrictions were removed For the same reason any exercise in which the individual engages must be suitable in type and degree to his ability to perform

The work done must itself have a purpose be that purpose ever so humble or simple It should be remunerative if the worker is not financially independent It is not so much a matter of the amount of the pay its value to the morale of the oldster is far beyond the dollars and cents involved Even in homes for the aged it has proved worth while to reward the guest for small chores performed to be able to jingle in his pocket a few coins he has earned is a great boost to his self respect

Retirement may be at the individual's choice In that case he may ask his physician "When shall I retire?" The important question however is not when to retire but what to do in retirement That question is easily answered by the man with many interests He can substitute his avocations and hobbies for his former job He can look forward to retirement as a welcome relief from less interesting work drudgery by comparison with doing the things for which up to now there has been little time But the question of what to do in retirement is a tragic one for him who has known only his job Riches alone are no solution In fact all too often the rich man has devoted himself so entirely to the making of money that he knows nothing else He thinks he will now turn to a hobby But hobbies should be started in youth and constantly cultivated through the years if they are to serve well later on (Let physicians themselves take note)

*Rest* in the proper doses is an increasingly needed restorer in later years The old need in the aggregate more sleep than in middle life But that does not mean that they need it all in one piece Since they tire easily, they are prone to indulge in several naps during the day This more than accounts for shorter sleep at night as a rule Yet this has given rise to erroneous claims by many old people that they sleep less than they did formerly The myth of Edison's 4 to 6 hours of sleep a day was dispelled after his death by the report of his laboratory staff who clocked his naps and found that he slept at least 8 hours in the twenty four

It is sound practice for the elderly to observe an early afternoon siesta This should be made a part of the routine of the working day Horizontal rest with or without sleep will improve efficiency in the latter part of the day and will avert the excessive fatigue that follows a day of unbroken activity

Vacations should be observed in longer periods with advancing years Even more

should they be multiple, rather than a single vacation annually. Except for the hottest part of the year, it matters little in which season the holiday is taken.

*Diversion.*—An indispensable ingredient in the formula of growing old happily is the possession of a wealth of inner and spiritual resources with which to occupy the increasing hours of leisure. Diversion unfortunately is today too often considered synonymous with amusement and amusement is becoming increasingly of the passive variety. Radio, television, and reading of the newspaper—of the comic strip variety—are robbing us of our capacity for active diversions. Yet it is far more soul satisfying to make music than to listen to it, to draw a picture or model a figure or even to whittle on a stick, to study some new subject or read a thought provoking book, article, or editorial, or to argue a timely topic with a friend, all this for at least a part of the time rather than to sit idly while others act, feel and even think for us.

But to do such things in our old age and especially to do them well, we must learn how to do them when we are young. Old age is something that everyone expects to attain. Moreover, most persons now being born will do so. Therefore education and training in youth, certainly as early as the high school level, should include this aspect of preparation for life.

The most valuable education is one which not only teaches an individual how to think and study, but how to continue self-education by self imposed disciplines after formal education ends. That goal is rarely achieved even at collegiate educational levels today. Yet in such self instruction lies a great source of happiness and satisfaction in the ever broadening mental horizon which it can bring throughout life, even when physical infirmity builds its increasing limitations.

Therefore, it is significant that public school systems are beginning to experiment in adult education by evening classes in the school buildings. They are offering a wide range of subjects, but with emphasis on cultural topics and the art of living. Herein lies real promise, for education is a never-ending process, not something that like growth must stop with most people in their teens. In fact there should be better results with adult students than are achieved in our schools and colleges with teen agers. We have proof of this in the records of G.I. students as compared with those of their less mature classmates.

A major tragedy in old age is the progressive loss of one's contemporaries. This must be compensated for as well as may be by regularly making new and younger friends, lest loneliness become overwhelming. The "youngest" old people are those who preserve a fresh outlook on life by cultivating contacts with the young.

Diversion then in old age depends in large measure on the inner resources that have been accumulated by the individual in his earlier years. The greater those resources the less is he dependent on others for diversion. But much can be done to plan group activities for the aged. Such programs are now being tried at community levels as a welfare activity, with a full time staff to organize groups under volunteer leaders in clubs, churches, neighborhood centers, to participate in entertainment, social gatherings, lectures, musicales, games and handicraft. An important benefit is the opportunity to make new friends. A fertile field for trying out such group activities is furnished by the homes for the aged that now shelter over half a million persons. The chief lack here, as the writer has found, is of trained social workers who have had experience in working with groups of the aged.

It must be emphasized that to work to best advantage and to enjoy diversion to the fullest, the aged must be provided with proper glasses, hearing aids, and dentures. This seems obvious, but the aged are all too often unable to provide these for themselves and hesitate to ask others to do so. It is the responsibility of children and other relatives to make such provision and it is up to the physician to remind them of this responsibility.

*Moderation* must constantly be stressed in advising both the aged and those who look after them. Moderation applies not only to work, rest, and diversion, but also to diet, habits, and personal hygiene.

*Diet* —The two most important dietary rules (and the two most commonly broken) are (1) that the caloric intake not be excessive and (2) that the diet be properly balanced

Obesity is the commonest disease in the United States The aged are particularly prone to it when one by one other physical pleasures have been outlived or denied and there remain only the joys of the table Yet obesity itself is the greatest single threat to longevity, as all mortality statistics show

Unbalanced diets are extremely common among the aged if the choice of food is left wholly to them This may be because poverty makes proper selection difficult or because poor dentition limits the range of acceptable foods or because the oldster yields to likes and caprice even more than do children and without the control that safeguards the latter, or because it is just too much trouble to cook a proper meal or to go out to eat Tea and toast diets are all too frequent Proteins and vitamins are commonly in inadequate supply Every form of dietary deficiency and in every degree is therefore encountered in the aged and represents another serious threat both to health and longevity Neither intelligence nor knowledge will always protect an oldster from falling into such foolish error This and the fact that such deficiency diseases in the elderly are easily mistaken for organic disease of other origins is shown in this example

A retired professor of a school of medicine wealthy, keen mentally robust in body, and well adjusted mentally (except perhaps that he was a bachelor and lived alone in a large house), began in his seventies to fail in health and strength, and *finally was admitted to a* hospital apparently in the last stages of some organic, probably malignant disease He was profoundly anemic edematous and lethargic *Yet after* transfusions symptomatic medication and proper feeding he rapidly returned to good condition and no organic disease could be found It then developed that for many months he had eaten nothing but tea and toast

The elderly, therefore need help and supervision in the selection of their diet Dental deficiencies must be *remedied* *Solid* foods that defy their dentures should be properly comminuted before being served Failure to do this is the commonest and most costly mistake made in *food service in* hospitals if any one doubts this statement, let him note the untouched meat on the outgoing tray in any hospital ward The trouble is that internes *residents and* nurses the people who order or serve the diets still have their teeth and so do not appreciate this handicap of the aged Moreover hamburg steak is much cheaper than tenderloin and just as nutritious

*Alcohol* is allowable in moderation It may stimulate gastric secretion and a flagging appetite If there be a threat of overeating, then an after-dinner highball can replace the pre dinner cocktail The vaso dilating and sedative effects of alcohol have actual and pleasant therapeutic value, as for example in mild angina But it is not well to prescribe alcohol for one who is opposed to it other and cheaper medicaments are available Excesses are not to be condoned, but one is reminded of Pepper s story about Benjamin Franklin then in his eighties who in remonstrating against his physician s order to give up alcohol pointed out that one sees more old drunkards than old doctors

*Tobacco* in the presence of heart disease especially coronary involvement and in case of peripheral arterial inadequacy should be prohibited Otherwise smoking should be allowed in moderation Here, too it is wise to ration the daily allowance *of the very old for they easily become chain* smokers Never should they be allowed to smoke in bed unless under supervision

*Sexual Intercourse* —Nature sets its limitations *in most instances* Here too moderation is the watchword But there comes to mind the old saying that an old man s three worst enemies are a well stocked wine cellar a good cook and a young wife

*Bathing* —The old should not be required to bathe oftener than once or twice a week The de fatting effect of soap on their dry and atrophic skin leads easily to eczema

*Care of the Bowels* —Constipation *is* common among the elderly So too is forgetfulness and this may give rise to an errone

ously high estimate of its severity. There fore some simple way of recording a bowel *movement* should be used. To relieve constipation, a mild laxative is far preferable to the indignity of an enema.

*Urination*.—Tycho Brahe, the great astronomer, lost his life because he feared to excuse himself in the presence of the Emperor of Austria and so developed acute retention. All old men and especially those with beginning symptoms of prostatism should void frequently. The writer remembers the advice received as a youngster from his family doctor, then in his eighties (B. I. Hinkle, Class of 1846, University of Pennsylvania): "My boy, void whenever you get the chance, whether you feel like it or not—you never know when the next chance is coming."

## SOME ADVICE TO LAYMEN WHO ARE RESPONSIBLE FOR THE AGED

This applies especially to children and other relatives of the aged.

The aged are best cared for and happiest in their own home. But if because of infirmity they must be moved into the home of a relative, or if the lone survivor of a couple must be so moved, then the room to receive them should be furnished as far as possible with things from the old home—pictures, trinkets, favorite chairs and table or desk—they are ties with the past. That room should be their palace, never to be entered without their permission, and to be treated as the symbol of the privacy that should be theirs.

Under no circumstances should a couple be separated. It is sheer cruelty even to send one parent to one child and the other to another.

The aged should be encouraged to continue and foster old friendships and old interest in their new surroundings. They and their friends should also be invited to some of the parties and functions of the household. They should be stimulated to do things and go places—to church, to club or lodge, to meetings, and to observe anniversaries and significant occasions.

They should be provided with some spending money, and preferably under some arrangement, even subterfuge, that it is something due them, in order to uphold their self respect. For the same reason they should be encouraged to observe neatness in dress and personal appearance. Nothing is so flattering as to seek their opinion and advice.

They should be given the chance to be useful by doing things in the household. Yet the bitter feeling of utter uselessness that plagues the aged is so often made worse by the young who find it easier to do something themselves rather than wait for it to be done by the aged. Even trifles mean much to them: for a decade an old man was happy in winding and regulating the clocks in the home, and he beamed each time they struck in unison.

Above all, they should be shown signs of affection. They are happiest in the knowledge that they are loved and welcome.

*Care During Illness*.—The aged person when ill should not be hospitalized unless circumstances demand it. His morale is best at home. The mention of hospital all too often strikes terror to his heart. Of course, if because of previous favorable experience he asks to go to a hospital, that objection is removed.

Whether at home or in hospital, the aged patient requires nursing care at night. Delirium, particularly during acute infections, tends to come on at night, although the patient be quite lucid throughout the day. Mental confusion, even in the absence of severe illness, is common at night, especially when an individual who has recently been moved to new quarters awakens and imagines himself elsewhere. Whether delirious or confused in the night, the oldster may get out of bed and do foolish or dangerous things. *In his attempt to go to the* bathroom as remembered in a former home or in an act of delirium, he may fall with serious or fatal result. Therefore, during severe illness a night nurse is more important than one by day. Always, whether well or ill, the oldster should have a *night light* burning, so that he can promptly orient himself.

Whenever possible, old patients should be

given bathroom privileges If that be not feasible, then the use of a commode at the bedside is still much less exhausting and much to be preferred to a bed pan

## SOME EFFECTS OF AN AGING POPULATION ON MEDICAL PRACTICE

The increasing percentage of the aged in the population is making changes in the complexion of the medical practice of today as compared with that of a generation ago Two noteworthy aspects of such changes are seen (1) in the greatly altered incidence of the kinds of diseases and (2) in the more subtle shift in the clinical picture of individual diseases

*Changing Incidence of Diseases* —In 1900 the nine leading causes of death were in this order (1) pneumonia and influenza (2) tuberculosis, (3) diarrhea (4) heart disease (5) kidney disease, (6) apoplexy, (7) cancer (8) bronchitis, (9) diphtheria In 1940, the list read as follows (1) heart disease (2) cancer, (3) deaths by violence (until 1948 the chief manner of violent death was by automobile but in 1949 this was the second cause of violent deaths the first being accidents in the home the elderly were responsible for this shift—in 1949 theirs constituted 40 per cent of the accidental deaths, of these 60 per cent were due to falls, and 86 per cent of the falls occurred in homes) (4) apoplexy (5) kidney disease (6) pneumonia (this will be much lower in 1950 statistics) (7) tuberculosis (8) prematurity (9) diabetes (in 1900 this cause was 27th on the list)

*Different aspects in the clinical picture of the same disease* are at times presented by the aged as compared with younger patients Diminished sensation modifies symptoms Fractures, lacerations and operative wounds are less painful and therefore early ambulation is easier with old patients Biliary colic is decidedly less common in the aged Gall stones may cause no pain even when they ulcerate through the gall bladder wall into the small intestine, which they may obstruct in the last foot of the ileum Turner has reported a case in which the ulceration occurred into the colon which was then obstructed by the stone measuring 2½ by 3 inches and weighing 5 ounces Peptic ulcers may be painless and unrecognized until they perforate or bleed Renal colic is often less severe As Rolleston has said, The organs in the aged suffer in silence

## SIGNIFICANT FACTS ON CERTAIN DISEASES AS SEEN IN THE AGED

Attention will now be called to some useful clinical facts about various diseases as they occur in the aged They will be taken up in some order by systems and groups There will be no complete descriptions of any disease that would be duplication of material in other sections of this textbook The purpose here is rather to give emphasis and perspective

*Old Age Itself* —Is old age a disease? No Ideally it is the natural cause of death a wearing out equally in all parts, like the one horse shay, an end without suffering, a falling asleep the old man, dozing in the sun sleeps more and longer and finally fails to reawaken Shelley has beautifully expressed it in Queen Mab '

Mild was the slow necessity of death
The tranquil spirit failed beneath its grasp
Without a groan without a fear
Calm as a voyager to some distant land
And full of wonder, full of hope as he

Like so many ideals this one too is rarely achieved Karsner made the comment that in 19 000 autopsies performed he had never seen a case of such natural death

*Cardiovascular System* —The cardiovascular diseases far outweigh in numbers and severity all others among the aged The chief ones are arteriosclerosis generalized and in local areas notably the cerebral apoplexy and myocardial sclerosis the arrhythmias coronary artery disease hypertension Since they are commoner in the aging than in those in earlier life their descriptions as found elsewhere in this work need no elaboration here

There is however an insufficient appreciation of the frequence and seriousness in the aging and the old of intravascular clotting and its consequence *thrombosis*

*and embolism* Coronary and cerebral thromboses are well enough recognized but more frequent and more often fatal are thromboses in numerous venous channels (leg veins hemorrhoidal and pelvic veins) and their secondary lesions in the lung Barnes has reported that 16 per cent of surgical deaths occurring in the Mayo Clinic are due to pulmonary embolism and infarction The routine use of preoperative anticoagulant therapy has prevented a fair proportion of such fatalities and the best results are noted in those over 60 years of age

In the arterial tree *mesenteric thrombosis* is one of the commonest of acute intra abdominal catastrophes in the aged Its greatest danger lies in delay of recognition and treatment Among the major triumphs of surgery in the aged are the patients who survive with ease the removal of large sections of intestine

*Kidneys* —Nephritis is comparatively rare in old age even though nephrosclerosis is frequent Therefore, in the presence of uremia in an old person, one should think first of an extra renal cause—some type of obstructive uropathy such as prostatism, stone benign or malignant tumor or stricture *Hematuria* is rather common In its presence, malignant disease must be ruled out, but it is frequently of benign origin—simple capillary hemorrhage such as not infrequently occurs in the skin or conjunctiva of the aged from slight trauma It is also at times associated with hypertension, much as is nose bleed Stengel used to emphasize this point in his teaching by the term *renal epistaxis*'

*Gastrointestinal Tract* —*Cancer* continues to be the most serious condition involving the digestive tract even into advanced years Its commonest sites are stomach, rectum and cecum Other parts of the colon the pancreas and the biliary tract account for many cases It should be emphasized that in the very old cancer tends to progress more slowly and is often latent Gastric cancer may become evident only through its metastases' In the cecum cancer by constant trickle bleeding brings about severe degrees of anemia that suggest blood dyscrasia especially Addisonian anemia, while the lesion is still relatively small

*Diverticulitis,* acute and chronic produces a variety of clinical pictures with elements suggesting infection, obstruction or neoplasm It is indeed a frequent precursor of cancer in the colon, where a third of such lesions surgically removed show carcinoma

*Appendicitis* in the aged tends to develop its symptoms less precipitously and so may simulate intestinal obstruction

*Gastric achylia* is the commonest abnormality in the digestive tract It is so often symptomless that its importance tends to be underestimated Yet it is essentially an evidence of atrophic gastritis It probably influences nutrition to a degree greater than is now recognized At times it gives rise to flatulent indigestion and to diarrhea It is often present in chronic gall bladder disease and may be a precursor of gastric cancer

*Acute (viral) hepatitis,* both the infectious and the homologous serum variety is not rare in the aged It tends to be more serious and protracted than in earlier life

*Respiratory Tract* —Chronic *bronchitis* is common in old age, and oftener on a less serious basis than in younger persons mild bronchiectasis poor circulation chronic infection, low-grade allergy associated paranasal sinusitis and excessive smoking are the most usual causes Nevertheless every case must be thoroughly studied to rule out more serious disease Roentgenography and bronchoscopy with aspiration of bronchial washings and examination of this material for malignant cells should early be employed to rule out tuberculosis and neoplasm

*Pulmonary tuberculosis* continues to be a serious problem in the aged not only from the individual point of view but especially from the standpoint of public health The highest mortality rate from this disease at any time of life is that of males over 65 Their fibroid phthisis moves slowly so that the true diagnosis goes unrecognized for months or years In the meantime the oldsters with their chronic bronchitis are careless in the disposal of sputum and so endanger all in the household Even when the diagnosis is made the patient often refuses to be isolated in a sanatorium

*Pneumonia*, lobular and lobar, is common among the aged though antibiotics and chemotherapy have been highly effective against it most of those who die of pneumonia are old people One reason for this is that *pneumonia may go unrecognized* longer in aged than in other patients It is an old observation that pneumonia in the aged and in the insane, may be practically afebrile The clinician who has once been embarrassed at the necropsy table by a full blown pneumonia that he had *never suspected thereafter examines more* carefully and regularly the lungs of his aged patients

*Endocrine Diseases —Diabetes* is the commonest endocrine disorder in the aged Its relative mildness and lack of symptoms are responsible for the fact that so many cases *are unrecognized their number in this* country is estimated at one million In hospitals which they enter for intercurrent disease, especially surgical conditions elderly diabetics are often unrecognized as such A urine specimen, collected in the early morning according to the usual hospital *routine is negative for sugar because of the* preceding all night fast But in the wake of the operation, the patient s sugar tolerance abruptly falls and in the obese, there may then develop an acidosis The diagnosis is established by the next examination of the urine It would be better to collect routine *urine specimens in hospitals an hour after* the main meal In the general population, there is need for yearly surveys especially among the elderly to discover the mild cases in order that proper treatment may forestall the various complications of diabetes In 1949 a radio program sponsored by the Philadelphia Diabetes Association brought several hundred new cases to hospital clinics

*Thyrotoxicosis* is not uncommon in old age It may present diagnostic problems especially if the gland is not *large* and *the eye signs* are minimal or absent In such cases the patient usually presents himself because of some secondary manifestation such as tachycardia, auricular fibrillation weight loss, or diarrhea, which may lead to an erroneous diagnosis of heart disease dysentery, or hidden neoplasm In the treatment of thyrotoxicosis in the aged, an important principle must be kept in mind it is dangerous to let the disease continue uncontrolled, lest the heart suffer irreparable damage Hence the best treatment is that which most promptly ends the thyrotoxic state Unless there are other contraindications this means surgical treatment, after the usual preparation In selected cases, it may be safe to use radio-active iodine, but it is not yet possible to assess its carcinogenic effect in the nodular goiters which occur in greater proportion among the aged

*Hypothyroidism* is also encountered in old age It may be mistaken for circulatory failure because of fluid retention bradycardia and mild breathlessness It must be remembered that pitting edema and effusion into the serous cavities including the pericardium may be due to hypothyroidism Another serious diagnostic error may arise in hypothyroid cases in which various mental symptoms chiefly depressive, are exhibited and are believed to be psychotic

Failure of sexual function is a normal accompaniment of aging But the worry which this engenders in some persons is of *pathologic importance The treatment is* by psychotherapy The attempts to restore potency and libido by measures ranging from the administration of hormones to glandular transplants are of doubtful value Even if they proved very successful one might still question the wisdom of putting *new wine into old bottles*

*Disorders of Metabolism and Nutrition — Obesity* is the chief menace to longevity, as well as the commonest disease in our population Its harmful effects on the cardiovascular system the pancreas the liver and the joints become greater with each advancing year Yet the older the patient, the harder it is to treat obesity Due almost always to eating too much obesity tends to increase as appetite continues unabated the means *to indulge it grow exercise diminishes* other pleasures become limited and (worst of all) the will to guard form and figure atrophies The treatment of obesity is important at any time but is most effective *before aging* has begun Its effectiveness depends of course upon the willingness of the patient to cooperate But the first responsibility lies with the physician who must record the

patient s weight at intervals, note early any trend to gain and then convince the patient that something must be done about it To do this, he may have to be brutal in telling the patient that he is digging his grave with his teeth

*Gout* is more frequent in the elderly than in any other group Its recognition is not difficult provided the physician is alert to the possibility The chief diagnostic stumbling blocks are (1) the simulation of rheumatic fever by early multiarticular attacks (fever leukocytosis rapid sedimentation rate) or other types of arthritis and (2) the fact that the blood s uric acid levels are usually normal except for short peaks that occur just before symptoms develop and have passed by the time the patient is first seen A therapeutic test with colchicin is most helpful

*Deficiency states* of various types and degrees are common in the aged Management of these states in the aged is the same as management of such states in younger persons

*Blood Dyscrasias* —*Anemia* is common in the aged and in its moderate forms usually has a dietary cause In the main it is anemia of the hypochromic microcytic variety Addisonian anemia may occur late in life Anemia is often secondary to neoplasm so that this differential diagnostic problem is presented by every case The anemia of neoplastic disease may be due to blood loss to depression of the bone marrow by toxic tumor products or to encroachment on the marrow by metastatic tumors, chiefly from prostate breast or thyroid or by primary tumors such as myeloma *Aplastic anemia* either primary aplastic anemia or that due to marrow exhaustion from other causes is relatively more frequent among the old than among the younger age groups *Chronic leukemias* are not uncommon In the old however they tend to progress more slowly and have longer remissions (especially is this true of chronic lymphatic leukemia) than is the case in younger patients *Acute leukemias* are rare Coagulation defects are infrequent but *purpura simplex* probably due to change in capillary walls and perhaps of dietary origin is not uncommon

*Skeletal Diseases* — *Arthritis* especially hypertrophic osteoarthritis and to a lesser degree rheumatoid arthritis, are diseases of advanced years A common bone disorder in the elderly is *osteoporosis* In part this is related to failing gonad function and suitable replacement therapy has proved helpful A major cause however, is disuse Long periods of confinement to bed are particularly likely to accentuate this trouble Ambulation and use, on the other hand are followed in a few weeks by perceptible recalcification It is futile to give calcium orally even in large doses *Paget s disease* occurs predominantly in later years there is neither a known cause nor an effective treatment Fortunately the progress of the disease is slow as a rule in those who continue to be active *Back pain* due to acute and chronic disorders of intervertebral discs is common in the old this explains many of the so-called cases of lumbago There is more virtue in preventing back pain than in curing it and this may be accomplished through regular exercises to keep the back muscles in condition and the avoidance of sudden and unusual demands on the back (the lifting of heavy weights strenuous work or exercise when not in condition and the like)

*Infectious Diseases* —Except for pneumonia and influenza infectious diseases are relatively uncommon among the aged This may be due at times or in part to acquired immunity but is usually due to infrequent exposure to infection For the aged may live long enough to lose an immunity acquired in childhood more grandmothers die of whooping cough for example, than do grandchildren In general the aged are rather poor risks when they do contract acute infections Tuberculosis in the aged has been discussed Syphilis in the aged is comparatively rare and its manifestations are less severe in them than in patients under 60

*Allergic Diseases* —Since easy sensitizability is the inborn defect that characterizes all allergic individuals the manifestations of allergy may begin as well as be present at any time of life Allergic diseases in the old however often differ in incidence,

type, and severity from such diseases in younger persons

The allergic person tends to lose some of his sensitivities as he grows older and to acquire fewer new ones There are several reasons for this It is the natural history of allergic disease that the intensity of a given sensitivity tends to wane in time and drop below the threshold level for the development of symptoms This may be through natural hyposensitization due to repeated small exposures It may be a matter of less frequent exposure because patients learn to avoid their allergens At all events, allergic diseases are generally less frequent in the aged than in the young

Certain types of allergic disease are less common than others among the old This applies especially to some of the more acute manifestations, such as hay fever urticaria, and migraine, and to food allergies Allergic digestive symptoms and headaches are also less common among the old the patient has learned to recognize and avoid the causes Contact dermatitis is less frequent too for in the old, the exposure incident to occupations is less varied and less intense

*On the other hand, some allergic disorders* occur with increasing frequency in the aged Their dry skin is likely to be subject to *allergic pruritus* and to *eczema due to various* sensitivities And though food allergies are less frequent among the old, there is greater exposure and hence *greater sensitization to drugs* among them The commonest drugs used by the aged are laxatives and phenolphthalein is an excellent sensitizer *Penicillin* sensitivity is rapidly increasing among persons of all ages, thanks to its routine use in every minor infection The serious reactions to gold in arthritics are also on an allergic basis

*Perennial nasal allergy* is frequent among the aged although not much complained of by the patient who has come to take his sneezes rhinorrhea and nasal blocking for granted It is also often overlooked by the physician who does not directly inquire about it The allergens most usually causing it are the inhalants, especially *the dust in* the patient's own home Common, too are the nasal complications of such long standing nasal allergy paranasal sinus infection and mucous polyps

Chronic respiratory infection and consequent bacterial sensitivity are *frequent in* those with perennial respiratory allergy This is responsible for the fact that *asthma* in the aged is more often continuous and chronic than it is in younger persons Infection tends to dominate the clinical picture chronic cough, purulent sputum recurrent low-grade fever exacerbations of asthma in the wake of acute colds

At this point a fact most important to the diagnosis of allergic diseases in the aged must be mentioned *the diminished reactivity of their skin to test materials* The reactivity of the skin to a given allergen decreases with the advancing years and may actually fail entirely, even though exposure of an extracutaneous shock organ to that allergen may still cause symptoms (for example goose feathers may cause asthma even though the skin reaction to them is negative)

Failure to understand this has given rise to the unfortunate and largely erroneous notion that asthma may be subdivided into *extrinsic* asthma (due to allergens outside the body) and *intrinsic* asthma (*due to a* cause within the body, notably infection) The frequent failure to get positive skin *reactions from elderly asthmatics* and the frequency of chronic respiratory infection in the aged have led to the assumption that *asthma* which begins late in life is practically always *intrinsic*—that is infectious and nonallergic in origin This is far from the truth

Sensitivity to external allergens if properly and thoroughly sought for can be established in most patients whose asthma begins in old age and such sensitivity should be suspected in the rest A frequent mistake is to assume that a patient whose asthma began in his advanced years is probably not an allergic person Yet questioning will often uncover other manifestations of allergy (excessive sneezing for example) that have troubled the patient since his early years and may even point to the probable nature of the allergens that now affect the bronchial tree in addition to the nose The frequent role of infection in asthma of the aged is not

denied but whether it is *solely* responsible for that asthma is seriously questioned

A word now about the treatment of chronic "intractable" asthma (not infrequently seen in the aged) with cortisone and ACTH Cortisone has brought as a rule only partial as well as transient relief to asthmatics In fact the hypoplasia of the adrenal cortex that follows the use of cortisone leaves the patient worse off than he was before And though ACTH has given complete relief for weeks or months the basic sensitivity to specific substances as demonstrable by skin test is not permanently set aside by ACTH and may cause a recurrence of asthma What is worse ACTH is itself a potent sensitizer if use of ACTH is discontinued and then after some weeks or months resumed the patient may be found highly allergic to it and may suffer a severe even a fatal reaction The use of ACTH in asthmatics should therefore be undertaken with full knowledge of its dangers and only after all other measures have failed

*Nervous System* —The aged are subject to many disorders of the nervous system mostly on a sclerotic and degenerative basis They call for no special attention here Only two organic conditions need be mentioned.

*Herpes zoster* is commoner in later than in middle years The point here to be stressed is the gravity of the condition not in its acute phase but in the residual pains that may last for months or even years and shorten by exhaustion the lives of persons previously robust and healthy Trigeminal involvements are especially trying Every effort should be made to give early and lasting relief if necessary nerve-block injections and necessary surgical procedures should be employed

*Paralysis agitans* is frequent progressive and distressing Because it is incurable it is also much neglected Yet much may at times be accomplished in alleviating its effects Various drugs may reduce the intensity of the tremor and should be tried singly and in combination They include strammonium belladonna barbiturates in small doses bromides and antihistamines Instruction in safety measures and in self help techniques should also be given the victims of paralysis agitans

*Functional nervous disorders* are common and of great importance in the aged Psychic and emotional stresses are frequent physical forces wane financial resources dwindle frustrations disappointments and tragedy are inevitable Hence functional troubles from simple psychoneuroses through psychosomatic pictures to the range of psychoses are met alone or in combination with various organic diseases

The physician must therefore be cautious in concluding either that the patient s troubles are wholly functional or that an existing organic lesion accounts for all his complaints

The mental capability of an aged person to enter into a contract financial marital or otherwise or to make a will has important medico-legal implications. The incompetence of children to assume such responsibility is recognized by law which has set age qualifications accordingly But no such limits are feasible for the aged although many reach the stage when they can no longer meet such responsibilities Under the law the aged are considered competent to the last unless legally proved otherwise

The aged are increasingly beset by difficulties and infirmities that make them less and less able to manage their affairs So they depend increasingly upon those about them children other relatives or strangers They tend to favor those on whom they depend and to be influenced by them in disposing of their possessions. Children as well as others may be devoted or neglectful altruistic or selfish So an old person often becomes the victim of designing sycophants (relatives or strangers) to the detriment of deserving members of the family or he quite competently decides to do more for kind strangers than for relatives who paid him no heed This leads to law suits in which the soundness of mind of the aged person at the time of action is questioned or the use of undue or improper influence upon him is alleged

Relatives must not only assume their responsibility toward their elders but realize that kindness is the best way to insure the good will of those elders and the protection

type, and severity from such diseases in younger persons

The allergic person tends to lose some of his sensitivities as he grows older and to acquire fewer new ones There are several reasons for this It is the natural history of allergic disease that the intensity of a given sensitivity tends to wane in time and drop below the threshold level for the development of symptoms This may be through natural hyposensitization due to repeated small exposures It may be a matter of less frequent exposure because patients learn to avoid their allergens At all events, allergic diseases are generally less frequent in the aged than in the young

Certain types of allergic disease are less common than others among the old This applies especially to some of the more acute manifestations such as hay fever urticaria and migraine and to food allergies Allergic digestive symptoms and headaches are also less common among the old the patient has learned to recognize and avoid the causes Contact dermatitis is less frequent, too for in the old the exposure incident to occupations is less varied and less intense

On the other hand, some allergic disorders occur with increasing frequency in the aged Their dry skin is likely to be subject to *allergic pruritus* and to *eczema* due to various sensitivities And though food allergies are less frequent among the old, there is greater exposure and hence greater *sensitization to drugs* among them The commonest drugs used by the aged are laxatives and phenolphthalein is an excellent sensitizer *Penicillin* sensitivity is rapidly increasing among persons of all ages, thanks to its routine use in every minor infection The serious reactions to gold in arthritics are also on an allergic basis

*Perennial nasal allergy* is frequent among the aged although not much complained of by the patient, who has come to take his sneezes, rhinorrhea and nasal blocking for granted It is also often overlooked by the physician who does not directly inquire about it The allergens most usually causing it are the inhalants especially the dust in the patient s own home Common, too are the nasal complications of such long standing nasal allergy paranasal sinus infection and mucous polyps

Chronic respiratory infection and consequent bacterial sensitivity are frequent in those with perennial respiratory allergy This is responsible for the fact that *asthma* in the aged is more often continuous and chronic than it is in younger persons Infection tends to dominate the clinical picture chronic cough purulent sputum recurrent low-grade fever, exacerbations of asthma in the wake of acute colds

At this point a fact most important to the diagnosis of allergic diseases in the aged must be mentioned *the diminished reactivity of their skin to test materials* The reactivity of the skin to a given allergen decreases with the advancing years and may actually fail entirely, even though exposure of an extracutaneous shock organ to that allergen may still cause symptoms (for example, goose feathers may cause asthma, even though the skin reaction to them is negative)

Failure to understand this has given rise to the unfortunate and largely erroneous notion that asthma may be subdivided into *extrinsic* asthma (due to allergens outside the body) and *intrinsic* asthma (due to a cause within the body, notably infection) The frequent failure to get positive skin reactions from elderly asthmatics and the frequency of chronic respiratory infection in the aged have led to the assumption that asthma which begins late in life is practically always *intrinsic*—that is infectious and nonallergic in origin This is far from the truth

Sensitivity to external allergens, if properly and thoroughly sought for can be established in most patients whose asthma begins in old age and such sensitivity should be suspected in the rest A frequent mistake is to assume that a patient whose asthma began in his advanced years is probably not an allergic person Yet questioning will often uncover other manifestations of allergy (excessive sneezing for example) that have troubled the patient since his early years and may even point to the probable nature of the allergens that now affect the bronchial tree in addition to the nose The frequent role of infection in asthma of the aged is not

the household Nor are members of the family unprejudiced or always reliable witnesses They too may exaggerate, minimize or hide information through sentiment or selfish design Every possible source of information should be used in cases that seem complicated or obscure

*Physical examination* and *laboratory aids* are therefore all the more important in arriving at a correct diagnosis in an aged patient

Our commonest mistakes are sins of omission failing to do what we should have done Most of them are included in *failure to make a regular and complete physical examination* A few examples of such sins are these taking the blood pressure in only one arm counting the pulse at the wrist not at the heart failing to count the respirations A patient was referred to the writer because of failure to respond to treatment for alleged Addison's disease The diagnosis was based on a blood pressure of 80/50 in the arm nearest the sphygmomanometer on the doctor s wall the hypotension was due to a vascular anomaly, the pressure in the other arm was 140/80 A rapid respiratory rate may point to pneumonia or circulatory trouble when other signs are minimal Temperatures measured in the mouth are useless in a dyspneic patient or one without teeth or with loose dentures or one that is loquacious or confused An unexplained anemia and leukocytosis in a hospitalized patient were finally traced to a large painless Vincent s ulcer under an upper plate

Failure to examine the genitalia and the rectum routinely is common in dealing with aged patients

The *laboratory* should be used more freely with the old to allow for the shortcomings of their medical histories and for the lesser symptoms of their organic diseases Of chief moment are routine blood count and urine analysis roentgenologic examination of chest digestive tract, skeleton and teeth determination of the blood s sugar and uric-acid levels Specialists especially the cystoscopist the proctoscopist and the bronchoscopist should be more commonly consulted about the aged patient than they are

## TREATMENT OF DISEASE IN THE AGED

Disease in the aged attacks old organs and tissues The objective of treatment therefore is to restore those structures to their current 'norm not to that of youth

*Medication* tends generally to be less effective in the old than in younger patients therefore not too much should be expected of it Since elimination of drugs is slower in the aged one must reckon with their *prolonged action* as well as their *cumulative effects* This calls for lower dosage This is especially true of opiates hypnotics, and even mild sedatives they should be given in smaller amounts lest their effect be prolonged beyond that which was intended The aged require smaller doses of digitalis This must be remembered in using powerful preparations like digitoxin since poisoning may follow a diuresis

Some drugs produce an *altered reaction* in the aged Hyoscyamine scopolamine and belladonna for example in addition to their usual effect at times induce delirium They should be used with caution and their effects noted, especially at night

The aged are prone to drink less of all fluids than do those in earlier years Hence special attention must be given to an *adequate water intake* by elderly patients receiving *sulfonamides*

*Vitamins* are more likely to be helpful than bitter tonics However the use of dilute hydrochloric acid (1 cc ) and pepsin (5 cc of essence of pepsin) frequently has gratifying results in those with achylia

*Cathartics* unless contraindicated by an existing lesion are preferable to enemas

*Surgery in the Aged* —Surgical treatment is yielding progressively better results in aged patients The record in fracture of the neck of the femur and that in prostatism are shining examples This improvement is due to a number of reasons—*better pre- and post-operative care better anesthesia better surgical technique* and *early ambulation*

The *most efficient therapeutic weapon* at the disposal of any physician in all phases of the care of the aged is sympathy The aged don t get too much of it at best A

of their possessions against predatory strangers When mental deterioration or other threat to capability arises there are proper legal steps which relatives can take to meet the situation

The physician has a frequent part to play in these matters He has the opportunity to study the aging person over the years and so can recognize early evidences of mental deterioration He also can learn much about the relations existing between that person and those about him If legal action ever arises, the physician is sure to be called to testify Therefore he should supplement *careful observation* of his aged patients with *carefully kept dated records*

*Surgical conditions* in the aged are not to be considered in detail in a medical text Their prevention however is an important function of the general practitioner in his care of the aging patient

*Hyperkeratosis* and *skin cancer* may be prevented by avoiding unnecessary exposure to sunlight Those with blond hair blue eyes, and a fair skin that blisters and peels instead of tanning should eschew sun worship, and should be increasingly careful as they grow older to avoid actinic rays including those of ' sun lamps

*Hernia* most often arises in youth or early maturity It should be surgically cured, not managed with a truss But all too often people wear a truss for many years As they grow older and gain or lose weight the old truss no longer fits Yet they refuse to change to a new one, but run increasing risk of strangulation, incarceration and other complications of hernia Those with trusses should be the most careful to avoid constipation Even in old age the best treatment for hernia is herniorrhaphy

*Cystocele rectocele, and uterine prolapse* should be repaired no later than the end of the child bearing period not only to insure better results but to prevent later cancer

*Gangrene* in extremities with poor circulation is better prevented by proper care of the feet than cured by mutilating surgical procedures On the other hand, in the presence of actual gangrene *amputation and return to some activity* are preferable in the old to indefinite hospitalization

*Accidents* are preventable Much needs to be done to safeguard the aged from injury by falling in their own homes The major hazards are throw rugs slippery stairs and floors loose toys articles left on a lower step to be ' carried up later' , long lamp and telephone cords stairs without proper banisters, and bathtubs and toilet seats without properly placed hand grips Night lights should be kept burning in home areas that the aged are likely to traverse at night

*Early ambulation* is especially important for the aged after operations injuries fractures and the like, to conserve strength and function and to prevent thrombosis and embolism

*Disorders of the organs of special sensation* are also outside the scope of this text Nevertheless, two of them are too important to be ignored in the most elementary discussion of the care of the aged *Presbyopia* is universal Everyone agrees that its correction is essential for the individual s safety as well as his functional capacity and happiness Nearly everyone is therefore willing to wear glasses and to have them checked and revised as needed But *deafness* which is extremely common and is even more of a handicap than defective vision certainly from the standpoint of happiness is all too often not corrected Moreover the physician doesn't advise a patient to select his glasses from the bargain counter of a department store neither should he send the deaf to a layman selling hearing aids The deaf should be sent to an otologist trained and equipped to select the proper device instruct the patient in its use, and counsel mastery of lip-reading

## DIAGNOSIS OF DISEASE IN THE AGED

The recognition of disease in the elderly has its peculiar problems

*History taking* is difficult The aged are forgetful and require detailed questioning Even so the information acquired is not always reliable The old often hide their symptoms if they are afraid that a confession of illness will jeopardize their employment At times the aged are guilty of malingering usually to gain sympathy but occasionally to inconvenience an unpopular member of

who by knowledge or experience may recognize their own portents (physicians, nurses, clergymen). He is too much concerned with the discomforts of the moment to realize that death is impending. Nor is it wise to tell him about it, except in the rare instances (homicide) in which an antemortem statement of legal import is at issue. In that case the law requires that the patient be informed of the probable imminence of his death and that he formulate his words in the light of that knowledge.

More frequent and in the aggregate more troublesome than pain are a number of lesser symptoms. Chief of these is thirst. In the dying it is complicated by the dry mouth and throat that make swallowing difficult or impossible. Minor degrees of breathlessness are frequent. Intensely annoying is the inability to cough up viscid secretions that accumulate in the trachea and pharynx. Failing strength prevents the patient from changing his position, with resultant distressing aches at pressure points.

Annoying, too, are the grief and hysteria of relatives unable to conceal their feelings. Zealous friends tax the patient with overlong visits and useless conversation. Whispering in the sickroom is more disturbing and disquieting than speaking in ordinary tones; what is not meant for the patient's ears should never be uttered in his presence.

The care of the dying, then, has several facets. The most important of these is nursing. A capable nurse who goes about her duties with quiet assurance sets the tone of the whole situation. In addition to the routine care required by any bed patient she must anticipate the needs which the patient is increasingly less able to express. Thirst is assuaged by frequent small sips of cool drinks—water, tart fruit juices, dry wine, carbonated water or champagne. Sordes and secretions in mouth and pharynx are removed with cotton-covered swabs dipped in glycerine. A suction apparatus can be very helpful. Frequent changes of position and shifting of supporting pillows relieve local discomforts. Cool sponging of the face and neck and the gentle use of a fan do much to relieve breathlessness and the sense of suffocation, and are not only more easily available but less annoying than an oxygen mask or tent. The nurse adjusts ventilation and illumination, keeping the light out of the patient's eyes—but drawing the shades only if there is photophobia—and keeping the temperature of the room cool. The weight of bed clothing may be lifted off the feet with a cradle, real or improvised. Woolen socks or stockings are more acceptable than heavy blankets. The use of electric light bulbs under a cradle is to be discouraged, but if tried should be most carefully watched and guarded because serious burns result at relatively low temperatures in legs with failing circulation.

The nurse can best control the attentions of the family and the visits of friends. A few old cronies, if welcome to the patient and if calm and cheerful in demeanor, may be permitted short stays at the bedside.

A special word is needed on behalf of the increasing numbers who die not at home or in a private room, but in the wards of hospitals. Hospital planning should include the provision of some degree of privacy for all patients: small wards (ten beds or fewer), semipartitions, the upper halves of glass and screenable, a nearby waiting room where relatives may sit out their vigil. A quiet room is useful for noisy patients or those requiring much attention, especially at night, and adds to the comfort and peace of mind of the other patients. It should not, however, be in direct view of or in communication with the main ward, lest it gain and hold an unsavory reputation in the minds of the rest of the patients. Transferring any patient to such a room for some casual reason in no way connected with an unfavorable prognosis may nevertheless arouse a sudden overwhelming fear of death in that patient. The writer remembers two such rooms that the ward patients knew as "Gates Ajar."

The role of the physician in the care of the dying has several aspects. His first concern is to shift the emphasis of treatment from curative to palliative measures. This does not mean the abandonment of all remedial procedures, but rather the avoidance of nuisance activities: operations that have nothing further to offer, needless tests, especially if they involve venipuncture

kindly approach, a patient ear for their troubles, and expressed appreciation of their problems, a cheerful word of reassurance and encouragement—these will often make the simplest remedies and procedures almost miraculously effective, absence of sympathy may render weak the most powerful measures that science affords

*The Care of the Dying* —This final task of the physician is well epitomized in the words of Worcester "Our duty to our patients ends only with their death and in the hours preceding there is much we can do for their comfort At the very least we can stand by them "

The physician should recognize the signs of impending death In a rapidly progressing illness these may appear with dramatic suddenness In a slow, wasting disease, their onset is often subtle and insidious They may therefore be overlooked or recognized too late by the physician for him to be of service in giving adequate warning to the family or to revise treatment in favor of comforting rather than curative measures

The family, or at least its responsible members need to be told that the patient is soon to die There are preparations to be made, relatives at a distance to be summoned, religious rites to be observed that make such warning necessary In the emergency, the physician may have to act for the family in summoning a clergyman of the patient s faith

But it is unwise to try to be too accurate in predicting the day and hour of death Such predictions often go wrong

There are various signs that warn of the approach of the end The most informative is the appearance of the face which Hippocrates describes in terms which have not been improved upon by his successors "A sharp nose, hollow eyes half open collapsed temples the ears cold contracted and their lobes turned out, the color of the whole face being green livid or lead-colored the lips relaxed pendant cold and blanched the mouth open cold sweats confined to the head, face and neck" And he further mentions the 'hands hunting through empty space, picking nap from the coverlet the hands and feet cold the belly and sides hot,' and the accumulation of secretions in the respiratory tract, when the "lungs discharge nothing, but are gorged with matters which boil as it were in the air passages Add to these the placidity of shock, with clouding consciousness shallow jerky breathing, a thin accelerating thready pulse that falls quickly away from the palpating finger a failing blood pressure a leaky skin and one has the full blown picture of impending dissolution Experience and an increasing knowledge of the prognosis in various diseases enable the physician to recognize the several features of this picture soon after their inception

Death comes oftenest at night, especially in the small hours after midnight when vital forces seem to be at their lowest ebb In the very old, death often takes over from his brother, sleep

Dying may be easy or hard, but in general it is easy It is easiest for those who die in sleep or suddenly It is easy in the deepening anesthetic coma that renal failure and acidosis induce at the end of the majority of diseases In most instances the severest suffering has usually ended hours or days before death Even in those whose last illness is commonly associated with severe pain as in coronary occlusion, there is often a complete remission of pain toward the end For example, a patient who had known the agonies of heart pain lived a whole day after the onset of his fatal coronary episode pulseless incapable of the least exertion, fully aware of his condition and its fatal outcome yet whispering of his great astonishment I have not the slightest discomfort

Death is hardest in a few rare conditions in which the mind is clear to the last while paralyses pain or convulsions predict and magnify the inevitable rabies tetanus strychnine poisoning acute ascending (Landry s) paralysis and a few others Equally distressing may be the suffocating dyspnea of a fast growing mediastinal tumor or status asthmaticus or acute bulbar poliomyelitis But such torments are less frequent in the aged than in those dying in earlier years

Fear of death itself is not often a major cause of distress for as a rule the patient is not aware that he will soon die (The commonest exceptions to this rule are those

it begins at birth and it ends at puberty, or at a convenient age (say 12 years) or when the patient is too tall to be put into a bed in the children's ward

But when does old age begin? At fifty, or sixty? There are those who are senile at forty, and others who are youthful at sixty five Or does old age begin with the involution of certain organs? Here again there is no definitive schedule ovarian function may cease in the thirties or late in the fifties The crystalline lens may lose much of its elasticity in the forties or not until the fifties or sixties The thymus atrophies in childhood Gray hair baldness, and the loss of teeth are not uncommon in the twenties yet the hair of the writer's father is not yet gray at ninety one The seeds of death are planted in us at our birth but the date of their fruition is unpredictable

But the chief reason that there will be few if any full time geriatricians is that no one admits that he is old until long after that fact is obvious to everyone else At a class reunion you note the doddering wreck that once was young John Doe and you congratulate yourself that you haven't slipped as he has Yet across the room John Doe is thinking the self same thoughts as he contemplates your state of decrepitude Each thinks the other a proper subject for a geriatrician's care but I go to a geriatrician I who am still barely middle aged? He who announces the limitation of his practice to geriatrics will probably starve

Every physician therefore must be a geriatrician in that the application of the principles of geriatrics must be part and parcel of his daily work Every physician must train himself to recognize in his patients the first evidences of old age He must look for the first signs of trouble in the apparently well for chronic diseases so often have their beginnings in the forties and fifties He must do what he can to retard the progress of aging and to mitigate and alleviate its effects *He should study* geriatrics while he is still young and has an objective point of view

drugs and modalities that can no longer be expected to produce benefits and only annoy the patient with painful pricks, injections, or uncomfortable positions But he should not fail to catheterize a distended bladder or tap a pleural effusion to ease the patient

The relief of pain is paramount Sedatives alone are rarely adequate if pain is severe Opiates should be used as needed, but it should be remembered that small doses are usually the most effective that morphine may be given under the tongue, and that crude preparations of opium administered orally may have a longer action than the alkaloids administered by injection Yet in severe pain morphine may give relief best when administered by intravenous drip (40 mg dissolved in 1000 cc of physiological saline solution and given at the rate of 100 cc an hour) Alcohol not only when taken orally, but even more so when given intravenously is helpful in relieving pain

The foods and fluids to be taken by mouth by the dying patient should be determined both in kind and amount by the patient s wishes and his ability to swallow When he no longer accepts these a judicious use of intravenous fluid may control thirst

The physician s visits brief but frequent should be calmly reassuring and reasonably cheerful Much the same principle should govern the demeanor of all who enter the sickroom The manner rather than the word conveys to the patient the comforting thought that he is not forsaken

Even when the patient is moribund the physician may be asked by the family for a consultation with another physician He should comply cheerfully and at once Early in his practice this writer upon receiving such a request from the wife of a patient two days before his death in the terminal uremia of chronic glomerulonephritis persuaded her against her will to drop the idea on the grounds that the outlook was hopeless and that such a consultation would involve a large fee and could do the patient no good Weeks later came a letter from the widow with this message You saved me a few dollars but you robbed me of the satisfaction that I might have cherished the rest of my life the thought that I had done everything possible for my husband in his last illness "

Should the physician ever speed the end and so reduce the patient s suffering? No Custom, tradition experience, social sanction, law and religion are unanimous in this and rightly so Euthanasia would be a long step backward in civilization Savages solved the problems of old age and chronic disease that way to use it now would be a return toward savagery It is a cherished axiom of the law of our civilization that a man is presumed innocent until proved guilty It is equally axiomatic in the practice of humane civilized medicine that a man is savable while he is still alive In these days of rapid advances in all branches of medicine next year next month tomorrow may bring the cure for the condition called hopeless today

But this does not mean that the physician should hesitate to give the normal dose of an opiate to relieve pain simply because there is danger that it might prove fatal to the patient in his weakened condition As strength ebbs, the margin between the therapeutic and the lethal dose grows ever narrower It is therefore to be expected that in some dying patient a proper dose of morphine given to control pain may induce a sleep from which he does not awaken With that contingency in mind the physician does well to summon a member of the family to see the patient before the opiate is given As to its possible effects the physician should be silent lest he be misunderstood

## GERIATRICS AND GERIATRICIANS

It is clear that a new specialty has arisen in medical practice the prevention and treatment of disease in the aged Will there be a new group of specialists geriatricians who limit their professional activities to this field? Ten years ago this writer did not believe so he is still of the same opinion

First of all it is impossible to define the limits of such a specialty for old age itself is not easily definable Those who would compare geriatrics to pediatrics forget that the domain of pediatrics is easily defined

it begins at birth and it ends at puberty, or at a convenient age (say 12 years), or when the patient is too tall to be put into a bed in the children s ward

But when does old age begin? At fifty or sixty? There are those who are senile at forty and others who are youthful at sixty-five Or does old age begin with the involution of certain organs? Here again, there is no definitive schedule ovarian function may cease in the thirties, or late in the fifties The crystalline lens may lose much of its elasticity in the forties or not until the fifties or sixties The thymus atrophies in childhood Gray hair baldness, and the loss of teeth are not uncommon in the twenties yet the hair of the writer s father is not yet gray at ninety one The seeds of death are planted in us at our birth but the date of their fruition is unpredictable

But the chief reason that there will be few if any full time geriatricians is that *no one admits that he is old until long after* that fact is obvious to everyone else At a class reunion you note the doddering wreck that once was young John Doe, and you congratulate yourself that you haven t slipped as he has Yet across the room John Doe is thinking the self same thoughts as he contemplates your state of decrepitude Each thinks the other a proper subject for a geriatrician s care but I go to a geriatrician I who am still barely middle aged? He who announces the limitation of his practice to geriatrics will probably starve

Every physician therefore must be a geriatrician in that the application of the principles of geriatrics must be part and parcel of his daily work Every physician must train himself to recognize in his patients the first evidences of old age He must look for the first signs of trouble in the apparently well for chronic diseases so often have their beginnings in the forties and fifties He must do what he can to retard the progress of aging and to mitigate and alleviate its effects He should study geriatrics while he is still young and has an objective point of view

drugs and modalities that can no longer be expected to produce benefits and only annoy the patient with painful pricks, injections or uncomfortable positions But he should not fail to catheterize a distended bladder or tap a pleural effusion to ease the patient

The relief of pain is paramount Sedatives alone are rarely adequate if pain is severe Opiates should be used as needed but it should be remembered that small doses are usually the most effective, that morphine may be given under the tongue and that crude preparations of opium administered orally may have a longer action than the alkaloids administered by injection Yet in severe pain, morphine may give relief best when administered by intravenous drip (40 mg dissolved in 1000 cc of physiological saline solution and given at the rate of 100 cc an hour) Alcohol not only when taken orally but even more so when given intravenously is helpful in relieving pain

The foods and fluids to be taken by mouth by the dying patient should be determined both in kind and amount by the patient s wishes and his ability to swallow When he no longer accepts these a judicious use of intravenous fluid may control thirst

The physician s visits, brief but frequent should be calmly reassuring and reasonably cheerful Much the same principle should govern the demeanor of all who enter the sickroom The manner rather than the word conveys to the patient the comforting thought that he is not forsaken

Even when the patient is moribund the physician may be asked by the family for a consultation with another physician He should comply cheerfully and at once Early in his practice this writer upon receiving such a request from the wife of a patient two days before his death in the terminal uremia of chronic glomerulonephritis persuaded her against her will to drop the idea on the grounds that the outlook was hopeless, and that such a consultation would involve a large fee and could do the patient no good Weeks later came a letter from the widow with this message You saved me a few dollars but you robbed me of the satisfaction that I might have cherished the rest of my life the thought that I had done *everything possible for my husband* in his last illness "

Should the physician ever speed the end and so reduce the patient s suffering? ## GERIATRICS AND GERIATRICIANS

*It is clear that a new specialty* has arisen in medical practice the prevention and treatment of disease in the aged Will there be a new group of specialists geriatricians who limit their professional activities to this field? Ten years ago this writer did not believe so he is still of the same opinion

First of all it is impossible to define the limits of such a specialty for old age itself is not easily definable Those who would compare geriatrics to pediatrics forget that the domain of pediatrics is easily defined

ages that the extent of physical disability in this nation will progressively increase

One of our great medical needs today is provision for total treatment of chronically ill patients in terms of the everyday problems of living Many such patients cannot be sufficiently rehabilitated in self-care to live independent dignified and happy lives at home

The problem of providing an integrated service for the chronically ill is a complex one There is one aspect of the problem that stands out glaringly at present the need in our general hospitals for training programs to enable many of the so-called chronic invalids to live independently at home The hospital must assume great responsibility for prevention of disease definitive treatment of diseases and rehabilitation after disease

The modern concept of medical rehabilitation was developed during World War II The rehabilitation programs of the military services and the Veterans Administration demonstrated that planned integrated programs of convalescent care stressing activity as an adjunct to definitive treatment could reduce the period of hospitalization offset the deconditioning phenomena of bed rest and prevent the harmful psychological sequelæ which often result from extended hospitalization The techniques of physical rehabilitation and retraining for the severely handicapped developed by the military services also have profound implications for the even larger number of our civilian population who are disabled

The Hospital Council of Greater New York has recommended that bed requirements for rehabilitation and convalescent care be placed at one bed per thousand of population This would mean that approximately 20 per cent of the beds in general hospitals would be utilized for this purpose It was felt by the Council that the allocation of this number of beds and the introduction of a dynamic rehabilitation program would decrease hospital days provide facilities for the evaluation and training of convalescent and chronically ill and disabled patients and would help provide a program of total medical care

Medical examination x ray and the usual hospital routines are not enough to meet the problems of the disabled persons Such patients must be taught to use their residual abilities to the maximum Patients must be tested and then trained in the activities of daily living—in the simple things like turning over in bed dressing and undressing applying and removing braces getting from the bed to the wheel chair or the standing position These are everyday things but they are the foundation of self-care and physical independence

The practice of rehabilitation begins with the belief that the doctor s responsibility does not end when the acute illness is ended or surgery is completed it ends only when the patient is retrained to live and work with what is left This basic concept of the doctor s responsibility can be achieved only if rehabilitation is considered an integral part of medical service Any program of rehabilitation is only as sound as the basic medical service of which it is a part The diagnosis and prognosis must be accurate for it is on them that the feasibility of retraining is determined

In addition to the general diagnostic studies the medical evaluation of the orthopedically handicapped must include muscle tests determination of joint range of motion and tests for the inherent needs in daily living In the physical medicine and rehabilitation service at Bellevue Hospital a check list of ninety six items is used to determine these factors They include (1) bed activities such as moving from place to place in bed and the ability to sit erect (2) toilet activities (3) eating and drinking (4) the ability to dress and undress—tying shoe laces manipulating buttons zippers and other fasteners and applying and removing braces (5) hand activities—winding a watch striking a match and using various door knobs and latches (7) wheelchair activities—getting from the bed to the wheel chair the wheel chair to the bed and in and out of the bathtub and (8) elevation activities which include the needed abilities for walking climbing and traveling (Fig 229)

At first glance such a test list sounds formidable and time consuming but the necessary information may be easily ob-

# Chapter 30

# Medical Practice and Rehabilitation

By HOWARD A RUSK M D

TODAY, as medical science moves forward in the prevention and cure of infectious disease, chronic illness has become the nation s primary medical problem In 1900, seven chronic diseases (cancer diabetes intracranial lesions of vascular origin diseases of the heart diseases of the arteries cirrhosis of the liver and acute and chronic *nephritis*) *were responsible for 25 7 per cent* of all deaths in New York State Between 1900 and 1940, a period in which the population of New York State increased by 85 per cent and the total number of deaths increased by only 13 per cent the number of deaths from this group of chronic diseases increased by 200 per cent and now includes over two thirds of all deaths in the state

*One of the principal causes of the in*creasing prevalence of chronic disease has been the great advances in medical and surgical care which have prevented death and produced an aging population Two thousand years ago the average length of life was 25 years, at the turn of the century it was 49, today it is 67 2 In 1900 one person in twenty five was 65 years of age or older, it is estimated that in 1980 the ratio will be one in ten The chances are now two out of three that a young man now starting his working life at the age of 18 will live to his retirement age of 65 A 45-year-old man today has seventy in 100 chances of reaching the age of 65 and the chances for a 55 year old man are seventy eight in one hundred White men now at the age of 65 can expect to live an additional twelve and a half years on the average and white women an average of fourteen and a quarter years

What are the medical and public health implications of this increasing age level of the population? First as people become older their medical needs change and they demand more medical service In 1940 the 26 5 per cent of the nation s population over 45 required over *half the nation s* medical care By 1980 it is expected that the number of persons over 45 will constitute nearly half the population Today, we are busily studying and discussing the need and the best plan for increasing and distributing medical services yet the growing age level of the population indicates that by 1980 we may need nearly double the amount of *medical service that is available today*

Secondly lacking specific measures in the cure of many of the chronic diseases medicine must look to rehabilitation to teach those afflicted by chronic disability to live and to work as effectively as possible with what they have left Until medicine finds specific answers to the problems of the diseases of the heart and circulation rheumatic fever and arthritis cerebral palsy multiple sclerosis poliomyelitis and the other crippling diseases we must utilize the techniques of physical rehabilitation psychology social service and other allied specialties of rehabilitation to teach the disabled to live within the limits of their disabilities but to the hilt of their capabilities

Until we find the etiology and treatment for the chronic diseases producing disability we can expect as the population

trained by a therapist nurse a well trained volunteer or a member of the patient s family From special check sheets used for charting the activity accomplishments information is readily available both on the status of the patient at the time of admittance and on his progress while undergoing rehabilitation

The use of such a check list is particularly helpful if personnel are not available to do definitive muscle testing and accurate range of motion determination for the daily activities test can be completed in the hospital the physician s office or the patient s home The subsequent training program is designed to teach the patient the various skills and activities which he cannot perform

After the basic medical work up the physician in conference with other staff members prescribes a five-hour a-day program for the patient This program includes training in all the ambulation and elevation rooms and the remedial gymnasium occupational therapy physical therapy speech therapy and any other activity which may be helpful in meeting the specific needs of the patient

In a comprehensive rehabilitation program vocational guidance specialists should also be available to do guidance work and testing in order that the patient may be started on a prevocational exploratory and work testing program as soon as it is medically feasible However good basic rehabilitation can be carried out with the personnel available in the ordinary general hospital if such a program is properly organized supervised and prescribed by the physician

The rehabilitation of the hemiplegic person is a typical example There are a number of simple progressive procedures in the rehabilitation of the hemiplegic who suffers from one of the commonest disabilities seen in general practice In the early stages of treatment the following devices should be used to prevent deformities (1) footboard or posterior leg splint to prevent foot drop, (2) sandbags to prevent outward rotation of the affected leg (3) a pillow in the axilla to prevent adduction of the shoulder (Fig 230) Quadriceps setting should also be instituted to maintain muscle strength The procedure is relatively simple and requires no special equipment Its use however will prevent crippling anatomic deformities and hasten the rehabilitation of the patient

The next procedure indicated is the institution of pulley therapy This can be done simply with a small pulley attached to a goose-neck pipe over the head of the bed ordinary clothesline being used with a 1inch (2 5 cm ) webbing for the hand loop With

FIG 223

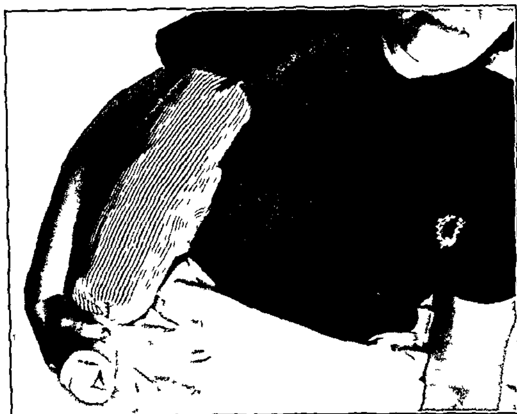

Fig 230 —A pillow placed in the axilla will prevent adduction of the shoulder

the stretching and passive exercise provided by pulley therapy the range of motion can be increased and adhesions prevented (Fig 231)

Pulley therapy has an advantage over the usual stretching exercises that are done passively for the patient knowing his own pain threshold will proceed to fully tolerated motion much more quickly Pulley therapy can also be used to aid in the reestablishment of reciprocal motion patterns

The patient at this stage should be encouraged to sit erect in order to reestablish balance Speech therapy if indicated should be instituted at this time In the absence of a trained speech therapist speech reeducation can be started under medical supervision by any teacher who has had some experience in this field In the case of aphasia it is well for the physician to point out to the patient and family the nature of the condition in order that the inability to use the tools of language may not be interpreted as loss or diminishing of the ability to think and reason

The next progressive stage in retraining the hemiplegic person is ambulation This should include (1) practice in balancing in the standing position and walking with the aid of parallel bars (2) learning a heel-and-toe gait to minimize clonus and reestablish normal walking habits *stressing reciprocal* motion and (3) using a short leg brace This last will be needed in approximately half the cases to correct foot drop (Fig 232) All the *equipment for training in ambulation* is simple and readily obtained by the general practitioner If parallel bars are not available two kitchen chairs may be used

*In the advanced stages* of retraining ambulation is continued with instruction in (1) crutch walking starting usually with the alternate four point gait and (2) elevation stressing climbing steps curbs stairs

DATE__________________

THERAPIST______________

practice in many hospitals after an amputation above the knee to elevate the stump on a pillow. However, if such elevation is maintained for as long as two weeks, a flexion deformity will occur which will take from six to eight weeks of arduous, painful work before sufficient hyperextension can be regained for satisfactory walking.

In advising his patient on the selection of a prosthetic device the physician must be aware that not all limbs are suitable for all amputees. In fact, he must realize that not all amputees can wear artificial limbs profitably. A person in the older age group with an amputation above the knee cannot, as a rule, profitably be trained to use a prosthetic device if he is unable to perform a swing through gait on crutches.

The physician must point out objectively to the patient those skills which the patient can expect to achieve with proper training and those skills which the patient has little chance of ever regaining. Extreme caution must be taken as to the latter, however, as it is unwise to tell a patient what he can't do, for this cannot be determined in most cases until the patient has had adequate training. Training is absolutely essential if the amputee is to be successfully rehabilitated.

Because of the hopeless outlook in multiple sclerosis, therapy in general has been directed toward symptomatic relief and the approach has been a negative one. In rehabilitation the disability rather than the specific disease process which has produced it is our primary consideration. In multiple sclerosis, as in any other chronic progressive crippling disease, the problems are the same.

Retraining in the basic physical skills of daily living is primary; it is simply a matter of first things first, for daily activity skills are the basis for all subsequent rehabilitation processes.

It has been found difficult in many instances to differentiate between muscular inability due to disease and that due to atrophy of disuse. Sometimes only a test period of conditioning exercise will provide this information, which is vital in the training program.

It has been noted, especially in hand activities and gait training, that persons long incapacitated from multiple sclerosis will have alienation and overcompensation of certain muscle groups. With muscle reeducation and definitive therapeutic exercise, it is often possible to accomplish much correcting these conditions.

The psychiatric-psychologic problem must be approached by the psychiatrist, the social worker and the psychologist working as a team with the family as well as with the patient. After the patient's personality is thoroughly known by psychiatric examination, psychologic study and social service investigation, then each problem, as it comes up, can be handled with the full knowledge of the limitations of the patient, psychologically and physically.

Multiple sclerosis offers one of the most challenging problems in the entire field of rehabilitation, both from the physical and psychological standpoint. Therapy in this field requires patient training and deep understanding.

Emotional trauma may be present in any patient who has suffered a severe physical disability. The sudden shock and realization of the possible economic and social consequences of permanent disability frequently produce fear and anxiety which become as handicapping to the worker as the original physical disability.

When patients present themselves who are in need of psychiatric attention, it is the responsibility of the physician to recognize that need and see that proper referrals are made for such attention. In many instances where emotional problems are of a less severe nature, the general practitioner can resolve such problems. One of his greatest responsibilities with those patients who have severe physical disabilities is motivation—encouraging and convincing the patient that he can be rehabilitated. This motivation, to be most effective, must begin at the earliest possible moment following the accident or illness. The physician who knows something of rehabilitation can start at the time of the accident or crippling illness to allay the fears of his patient by giving him understanding, courage and hope predicated on an accurate knowledge of what

Fig 231 —Stretching and passive exercise provided by pulley therapy increase range of motion and prevent adhesions

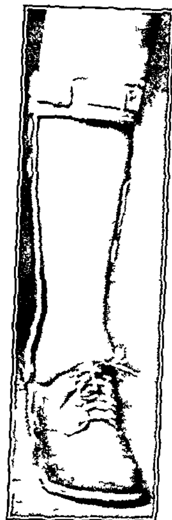

Fig 232 —A short leg brace is needed in approximately half of cases to prevent foot drop

and ramps Concurrently with the training in ambulation attention should be given to retraining in the activities of self-care and daily living

Obviously the physician himself cannot undertake the actual administration of the retraining but the therapist nurse volunteer or even a member of the patient's family can conduct the activities under the physician's supervision With such a program many of the complications usually following apoplexy can be avoided and a great deal of time and ability salvaged

Although the general practitioner is forced to call on the services of medical specialists when dealing with amputee patients, he must assume the responsibility for preparing his patient physically and psychologically for the amputation and for seeing that the patient has the proper prosthetic device adequately fitted and is trained in its use

One phase of the management of the amputee to which the physician should give particular attention is the immediate post operative period while the stump is being shrunken in preparation for a prosthetic device During this period of six or eight weeks the patient should be given graduated conditioning exercises in preparation both for crutch walking and for the later use of the artificial limb Measures should be taken to prevent anatomic deformities

For example it is not an uncommon

practice in many hospitals after an amputation above the knee to elevate the stump on a pillow However if such elevation is maintained for as long as two weeks a flexion deformity will occur which will take from six to eight weeks of arduous, painful work before sufficient hyperextension can be regained for satisfactory walking

In advising his patient on the selection of a prosthetic device the physician must be aware that not all limbs are suitable for all amputees In fact, he must realize that not all amputees can wear artificial limbs profitably A person in the older age group with an amputation above the knee cannot, as a rule profitably be trained to use a prosthetic device if he is unable to perform a swing through gait on crutches

The physician must point out objectively to the patient those skills which the patient can expect to achieve with proper training and those skills which the patient has little chance of ever regaining Extreme caution must be taken as to the latter however as it is unwise to tell a patient what he can t do for this cannot be determined in most cases until the patient has had adequate training Training is absolutely essential if the amputee is to be successfully rehabilitated

Because of the hopeless outlook in multiple sclerosis therapy in general has been directed toward symptomatic relief and the approach has been a negative one In rehabilitation the disability, rather than the specific disease process which has produced it is our primary consideration In multiple sclerosis as in any other chronic progressive crippling disease the problems are the same

Retraining in the basic physical skills of daily living is primary it is simply a matter of first things first for daily activity skills are the basis for all subsequent rehabilitation processes

It has been found difficult in many instances to differentiate between muscular inability due to disease and that due to atrophy of disuse Sometimes only a test period of conditioning exercise will provide this information which is vital in the training program

It has been noted especially in hand activities and gait training that persons long incapacitated from multiple sclerosis will have alienation and overcompensation of certain muscle groups With muscle reeducation and definitive therapeutic exercise, it is often possible to accomplish much correcting these conditions

The psychiatric psychologic problem must be approached by the psychiatrist the social worker and the psychologist working as a team with the family as well as with the patient After the patient's personality is thoroughly known by psychiatric examination psychologic study and social service investigation then each problem, as it comes up can be handled with the full knowledge of the limitations of the patient psychologically and physically

Multiple sclerosis offers one of the most challenging problems in the entire field of rehabilitation both from the physical and psychological standpoint Therapy in this field requires patient training and deep understanding

Emotional trauma may be present in any patient who has suffered a severe physical disability The sudden shock and realization of the possible economic and social consequences of permanent disability frequently produce fear and anxiety which become as handicapping to the worker as the original physical disability

When patients present themselves who are in need of psychiatric attention it is the responsibility of the physician to recognize that need and see that proper referrals are made for such attention In many instances where emotional problems are of a less severe nature, the general practitioner can resolve such problems One of his greatest responsibilities with those patients who have severe physical disabilities is motivation—encouraging and convincing the patient that he can be rehabilitated This motivation to be most effective must begin at the earliest possible moment following the accident or illness The physician who knows something of rehabilitation can start at the time of the accident or crippling illness to allay the fears of his patient by giving him understanding, courage and hope predicated on an accurate knowledge of what

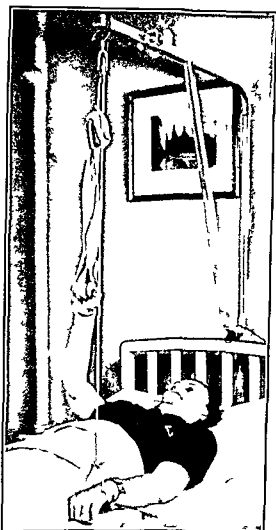

FIG 231 —Stretching and passive exercise provided by pulley therapy increase range of motion and prevent adhesions

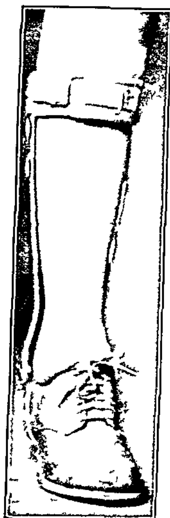

FIG 232 —A short leg brace is needed in approximately half of cases to prevent foot drop

and ramps Concurrently with the training in ambulation attention should be given to retraining in the activities of self-care and daily living

Obviously the physician himself cannot undertake the actual administration of the retraining but the therapist nurse volunteer or even a member of the patient's family can conduct the activities under the physician's supervision With such a program many of the complications usually following apoplexy can be avoided and a great deal of time and ability salvaged

Although the general practitioner is forced to call on the services of medical specialists when dealing with amputee patients, he must assume the responsibility for preparing his patient physically and psychologically for the amputation and for seeing that the patient has the proper prosthetic device adequately fitted and is trained in its use

One phase of the management of the amputee to which the physician should give particular attention is the immediate postoperative period while the stump is being shrunken in preparation for a prosthetic device During this period of six or eight weeks the patient should be given graduated conditioning exercises in preparation both for crutch walking and for the later use of the artificial limb Measures should be taken to prevent anatomic deformities

For example it is not an uncommon

# DISEASES OF THE NERVOUS SYSTEM

## Chapter 31

## Diseases and Abnormalities of the Mind Including the Neuroses[1]

By EDWARD A. STRECKER, M.D. and MANUEL M. PEARSON, M.D.

### THE PSYCHOSES

#### INTRODUCTION

THE mode of presentation of the diseases of the mind to the physician and the medical student has become somewhat formalized. The praiseworthy effort to attain completion often results in unduly lengthy discussions and fails to place proper emphasis on those conditions that are commonly encountered in practice. After all, while a description of paranoia makes fascinating reading, it is so rare that the physician may go through a lifetime of practice without meeting a single instance. Much more important is a thorough understanding and appreciation of schizophrenia, which is, perhaps, the most common psychosis, or paresis, which in its early stages is vulnerable to intelligent therapeutic attack. Multiple personality in hysteria provides material for engrossing speculation, but much more practical for the doctor is the knowledge of the common neuroses and their everyday manifestations. It is the opinion of the authors that *the neuroses and neurotic additions to organic disease constitute about 70 per cent of the practice of medicine*. Of overwhelming importance is the capacity to understand and to utilize therapeutically the fundamental fact that in every illness, no matter how purely *physical* it may seem to be in its manifestations, there is nevertheless an important *mental* component which must be thoroughly understood and energetically treated.

It is a grave mistake to isolate psychiatry. It is part and parcel of internal medicine. When one remembers that the human being is a *total organism*, with various physiologic and psychologic levels, and that the whole organism must always be studied in reference to the environment, it is easy to appreciate that so-called mental symptoms are often only manifestations of causes which in other instances or even in the identical patient may produce fever, alteration in the pulse rate and the like. Thus infection, fever, exhaustion, toxic agents like alcohol,

[1] The authors acknowledge the courtesy of being permitted to quote from Practical Clinical Psychiatry, Strecker, Ebaugh and Ewalt, 6th ed., P. Blakiston's Sons & Co., 1935 and 1940, and Fundamentals of Psychiatry, by Strecker, J. B. Lippincott Company, 1942.

can be done He can interpret to the patient the findings of the specialist in words that are understandable and meaningful He can explain to the patient the nature and extent of his disability, not in medical terms of the disability alone, but in terms of its effect on the vocational, social, economic family and personal life of the patient The physician must practice the art of medicine as well as the science

Regardless of the type of disability, the responsibility of the physician to his patient cannot end when the acute injury has been cared for It ends only when the physician has taken the responsibility for seeing that proper referral has been made to those agencies and institutions which are equipped to rehabilitate and retrain the patient with a residual physical disability

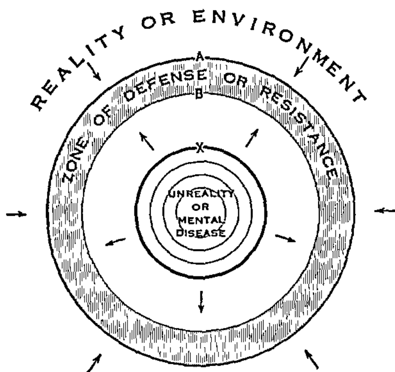

FIG 233

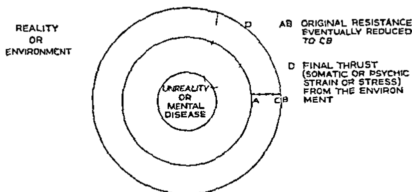

FIG 234

FIGS 233 and 234 —In figure 233 a normal amount of resistance against mental disease is indicated by the line A–B It is to be noted that this is in perfect contact with reality or environment at every point Unreality or mental disease and its various degrees of severity is indicated by the inner circles (From Clinical Psychiatry by Strecker and Ebaugh 5th edition Philadelphia P Blakiston s Son & Co 1940 )

measurable and concrete but probably they inflict more devastating mental damage Disappointment in love marital difficulties business reverses and many other situations cannot be observed in a test tube or viewed under a microscope but often they produce *anxiety* the effects of which may be observed as it saps the mental resistance and ends in mental disease

The recital of the causes of mental disease must not lead to narrow and restricted thinking Man presents various levels of functioning physical and mental These are distinguished by increasing complexity For instance at the lowest physical level there is the exercise of somewhat automatic functions like respiration at the higher levels one might consider voluntary motor activity

drugs, certain metals and gases, the more chronic intoxications like lues and tuberculosis, metabolic disease and arteriosclerotic disturbances or endocrine imbalances, all have mental components or symptoms which are really not separable from physical phenomena Conversely that whole group of experiences ordinarily called "emotional unquestionably influence the clinical pictures and even to some extent, the course and outcome of organic disease whether it be eczema or typhoid fever As a matter of fact, there is no dividing line between psychiatry and internal medicine Furthermore, unless there is penetrating study the symptoms of organic disease on the one hand and functional disease on the other, are often not distinguishable as to underlying causation For instance a patient with headache and projectile vomiting who barely escaped exploratory operation for brain tumor made a prompt recovery when the emotional conflict at the bottom of his symptoms was efficiently treated by psychotherapeutic measures The *current focussing* of attention upon psychosomatic medicine constitutes an acceptance of the principles of psychiatry In the area of psychomatic medicine there may be found numerous clinical proofs of fundamental psychiatric lessons That since man is a *total organism* somatic reactions are accompanied by appropriate emotional patterns and, *vice versa*, emotional experiences are at once reverberated in every tissue and cell of the body Finally, it has been demonstrated that too long continued disordered function due to unresolved emotional conflict eventuates in tissue pathology as in many instances of peptic ulcer (*See* Chapter 27)

### General Considerations

*Etiology*—In the consideration of the individual psychoses the causal and determining agents will be stressed, but at this point a broader and more philosophic view point may not be amiss In the final analysis mental disease and indeed all disease is due to the overthrowing of resistance Resistance against mental disease at any given point in the life history of an individual is determined by the sum total of his previous experiences (including ancestral assets and liabilities) and his reaction to them The vulnerability of this resistance is extremely variable not only from person to person but also it varies during the life cycle of the same individual, and finally, it differs according to the amount of the particular resistance which may be developed against this or that specific threat to mental stability

The resistance may be abruptly destroyed or it may be insidiously undermined Some simple diagrams may be illustrative (p 1407)

When the physician sees a patient who is mentally or nervously sick he is witnessing the end result of a serious disturbance of the normal relationship between that patient and his environment It is easy to understand how this balance representing normal mental health, may be upset not only by such physical agents as syphilis or arteriosclerosis of the brain but also by the factors ordinarily denominated emotional as *for instance* the stress and strain of prolonged fear or worry, or more remotely by lack of training during childhood so that problems of adult life cannot be met

More particularly the causes of mental diseases may be divided into those factors that are *predisposing* and those that are *exciting* The predisposing factors such as inheritance, critical age epochs like adolescence, the menopause or senility environmental factors such as defective childhood training occupation for instance contact with the various industrial poisons like white lead and a previous attack of mental disease favor the likelihood of the development of mental illness

The exciting causes actually *determine* the occurrence of the mental disease They may be chiefly physical or chiefly emotional The physical factors include fever toxicity of infection exhaustion exogenous intoxications such as may be due to alcohol drugs and the various industrial poisons the endogenous intoxications as, for instance in kidney liver or other disorders chronic toxicity notably due to lues metabolic disturbances endocrine dyscrasias and trauma

The emotional exciting causes are less

an psychoanalytic catharsis is a highly specialized technic that investigates the unconscious psyche (beyond the scope of the awareness of the patient) and through the interpretation of the everyday behavior, free association and the dream life seeks to give the patient enough self knowledge so that he may sever the bonds of restricting fixations become free of his symptoms and emotionally mature

### Classification

In psychiatry nosology faces even greater obstacles than it does in internal medicine The body of information from which a classification scheme must be built is creditably large but unfortunately it is not homogeneous For instance paresis in its etiology pathology and symptoms is as clearly understood as is typhoid fever or tuberculosis but on the other hand schizophrenia remains an unsolved riddle yet it must be fitted into any list of mental diseases

The accompanying grouping is based on a simple division into

(a) Organic
(b) Toxic
(c) Functional or psychogenic

Certain psychoses are predominantly organic that is they present pathologic alterations in the structure of the brain other psychoses are predominantly toxic in other words the symptoms are produced by bodily intoxication either by poisons introduced into the body from without (for instance alcohol), or by poisons created within the organism (uremia) finally in some psychoses the important factors seem to be functional or psychogenic

Naturally such a classification is far from conclusive As more knowledge is gained unquestionably there will be shifting from the organic to the toxic group and *vice versa* Even at this writing it is obvious that even in the most clear-cut organic psychosis (paresis) there are frequently toxic manifestations while as an aftermath of toxic reactions one often witnesses permanent structural alterations Furthermore the functional or psychogenic group as a whole will scarcely stand the test of time since even now many interesting organic and toxic manifestations have been recorded Finally the student must always remember that the prepsychotic personality of the individual may color deeply the expression of any psychosis

The psychoses that are starred will be described in some detail Wherever reliable statistics are available percentage frequency is given

*Examination and Symptoms* —The psychiatrist has no quick devices reliable short-cuts and but few instruments of precision at his command Master and student alike must utilize comprehensive and detailed history and conscientious examinations as a basis for sound and scientific opinion concerning diagnosis prognostic possibilities and treatment

The steps of history taking and physical examination cannot be given in detail The student will find adequate guides in any standard textbook [1]

Briefly the examination of the patient may be divided into the indirect examination or the history and the direct examination

It is particularly dangerous to neglect the *history* in psychiatry There are no instruments of precision by means of which the historical information may be discounted Unless the history is adequate important diagnostic clues will be lost For instance a record of lues suggests that the mental symptoms may be paretic of convulsions that the psychosis may be epileptic of recurring and transient blindness or deafness that it may be hysteria

The history may be conveniently divided into the account of the complaint of the present illness of the past history comprising the birth and developmental data the health record the school record the work record the sex development interests and habits and previous attacks of the personality and of the family

In psychiatric histories the history of sex is enormously important since there is scarcely a psychosis into which this elemental instinctive drive does not intrude

[1] The authors use the method outlined in Practical Clinical Psychiatry by Strecker Ebaugh and Ewalt 6th ed Philadelphia The Blakiston Co 1947

At the lower mental levels one witnesses the operation of the instinctive drives like self preservation and the physical sex urge, at the higher, there are ethical operations such as self-control or inhibition Though these various levels may be clearly recognized yet *even more important is the fundamental* fact that they are entwined into a *unit organism* In the instance of mental disease an exciting cause may enter at any level toxicity at a physical threshold as in pneumonia or anxiety at an ethical platform as in the case of a young officer in France who developed serious anxiety crises because he feared he might needlessly jeopardize the lives of his men as he led them into action In any event irrespective of the *level first involved the effect is to flood the* entire being and the individual is sick not only in mind and body, but in *all his mind and all his body*

Psychiatric thought tends more and more to the genetic dynamic approach The most clear-cut evolution in the study of mental disorder has been the recognition of the continuity of mental life in relationship not only to the organic growth of the individual but to the experiences which he undergoes and survives *A mental disorder* is to be studied from the earliest beginnings and as a stage to stage process The genetic dynamic approach so adequately formulated by Adolph Meyer does not regard the present difficulties and symptoms of the patient as the only or even the main objectives of study, but only one part of the large series of things which later must be studied from the earliest beginnings and dealt with as a whole

*Heredity* —Unquestionably inheritance is influential in the genesis of mental disease but its influence must not be overrated It should be remembered that in psychiatry, one must not expect Mendelian accuracy concerning heredity nor even that likelihood of transmission that attends such human defects as Huntington s chorea or family paralysis At the present stage of its development psychiatry will derive greater profit from the biometrician from clinical observation and from a study of environment than from a rigid interpretation of the inheritance factor

*Diagnosis and Prognosis* —To type a psychosis or neurosis according to certain diagnostic formulas and slavishly *to* prognose strictly according to the diagnostic label means little or nothing In no field of medicine is it more important to take into account the personal equation to consider first the patient and not be too much frightened *by the name of the psychosis* For instance schizophrenia may be hopelessly malignant, but in many instances a careful review of the life history may reveal many hopeful prognostic indications

*Treatment* —Under each psychosis the chief lines of therapeutic endeavor will be indicated, but there should be some brief mention of (*a*) prophylaxis and (*b*) psychotherapy

*Prevention* —Psychiatry abounds in opportunities for the institution of preventive measures Every patient should be viewed from this angle Never a case of paresis but that it should teach the importance of lessening the incidence of syphilis never an instance of schizophrenia but that its study should yield safeguards applicable to the training of children never a neurotic patient but whose life history should teach the prophylactic importance *of a better* contact between individual and environment

*Psychotherapy* —Psychotherapy is *not*, as popularly supposed a kind of mental sleight-of hand or miracle working that magically relieves patients *of symptoms* It is the important therapeutic weapon of the psychiatrist It is regrettable that it is not more generally employed in internal medicine Psychotherapy has very broad limitations It may be defined as an attempt to influence in the right direction the attitude of the patient that is to influence his attitude toward himself toward his mental *and physical processes and toward* his environment It is an effort to teach him to understand himself his illness and the cause or causes of his illness whether this cause or these causes lie in his body, in his environment or in the superficial or deeper layers of his mental life Persuasion suggestion useful habit formation self understanding strengthening of *morale are* all valuable psychotherapeutic methods Freud

ian psychoanalytic catharsis is a highly specialized technic that investigates the unconscious psyche (beyond the scope of the awareness of the patient) and, through the interpretation of the everyday behavior, free association and the dream life, seeks to give the patient enough self-knowledge so that he may sever the bonds of restricting fixations, become free of his symptoms and emotionally mature.

### CLASSIFICATION

In psychiatry, nosology faces even greater obstacles than it does in internal medicine. The body of information from which a classification scheme must be built is creditably large but, unfortunately, it is not homogeneous. For instance, paresis in its etiology, pathology and symptoms is as clearly understood as is typhoid fever or tuberculosis, but, on the other hand, schizophrenia remains an unsolved riddle; yet it must be fitted into any list of mental diseases.

The accompanying grouping is based on a simple division into:

(a) Organic
(b) Toxic
(c) Functional or psychogenic

Certain psychoses are predominantly organic, that is, they present pathologic alterations in the structure of the brain; other psychoses are predominantly toxic, in other words, the symptoms are produced by bodily intoxication either by poisons introduced into the body from without (for instance, alcohol) or by poisons created within the organism (uremia); finally, in some psychoses the important factors seem to be functional or psychogenic.

Naturally, such a classification is far from conclusive. As more knowledge is gained, unquestionably there will be shifting from the organic to the toxic group and *vice versa*. Even at this writing it is obvious that even in the most clear-cut organic psychosis (paresis) there are frequently toxic manifestations, while as an aftermath of toxic reactions one often witnesses permanent structural alterations. Furthermore, the functional or psychogenic group as a whole will scarcely stand the test of time since even now many interesting organic and toxic manifestations have been recorded. Finally, the student must always remember that the prepsychotic personality of the individual may color deeply the expression of any psychosis.

The psychoses that are starred will be described in some detail. Wherever reliable statistics are available, percentage frequency is given.

*Examination and Symptoms.*—The psychiatrist has no quick devices, reliable short cuts and but few instruments of precision at his command. Master and student alike must utilize comprehensive and detailed history and conscientious examinations as a basis for sound and scientific opinion concerning diagnosis, prognostic possibilities and treatment.

The steps of history taking and physical examination cannot be given in detail. The student will find adequate guides in any standard textbook.[1]

Briefly, the examination of the patient may be divided into the indirect examination or the history and the direct examination.

It is particularly dangerous to neglect the *history* in psychiatry. There are no instruments of precision by means of which the historical information may be discounted. Unless the history is adequate, important diagnostic clues will be lost. For instance, a record of lues suggests that the mental symptoms may be paretic; of convulsions, that the psychosis may be epileptic; of recurring and transient blindness or deafness, that it may be hysteria.

The history may be conveniently divided into the account of the complaint, of the present illness, of the past history comprising the birth and developmental data, the health record, the school record, the work record, the sex development, interests and habits and previous attacks, of the personality and of the family.

In psychiatric histories the history of sex is enormously important since there is scarcely a psychosis into which this elemental instinctive drive does not intrude

[1] The authors use the method outlined in Practical Clinical Psychiatry, by Strecker, Ebaugh and Ewalt, 6th ed., Philadelphia, The Blakiston Co., 1947.

A Organic Psychoses

| | | |
|---|---|---|
| 1 | Traumatic psychoses | 0 3 per cent |
| 2 | Senile psychoses | 12 1 per cent |
| *3 | Psychoses with cerebral arteriosclerosis | 6 4 per cent |
| *4 | General paralysis (paresis) | 10 6 per cent |
| 5 | Psychosis with cerebral syphilis | |
| 6 | Psychoses with Huntington s chorea | |
| 7 | Psychosis with brain tumor | |
| 8 | Psychoses with other brain or nervous diseases (Cerebral embolism paralysis agitans *meningitis tubercular* or other forms multiple sclerosis tabes dorsalis acute chorea encephalitis lethargica and other neurologic diseases ) | *1 2 per cent* (items 5–8) |
| *9 | Epileptic psychoses | 2 7 per cent |
| 10 | Psychoses with mental deficiency | 3 3 per cent |

B Toxic Psychoses

| | | |
|---|---|---|
| *11 | *Alcoholic psychoses* (This figure based on comparative admissions to the State hospitals in the United States in 1920 In 1922–1923 of 4444 consecutive admissions to the Psychopathic Wards of the Philadelphia Hospital 10 8 per cent had alcoholic psychoses ) | *2 2 per cent* |
| 12 | Psychoses due to drugs and other exogenous toxins | 1 1 per cent |
| 13 | Psychoses with pellagra | 0 37 per cent |
| 14 | Psychoses with other somatic diseases *(Including delirium with infectious disease postfectious psy*chosis exhaustion delirium delirium of unknown origin cardio renal disease diseases of the ductless glands epidemic encephalitis other diseases or conditions ) The percentage figure is undoubtedly too low It is based on admissions to public mental hospitals The majority of these psychoses are encountered in general hospitals in sanitoria and in private practice | 2 81 per cent |

C Functional (Psychogenic) Psychoses

| | | |
|---|---|---|
| *15 | Manic depressive psychoses | 16 0 per cent |
| *16 | Involutional melancholia | 3 2 per cent |
| 17 | Schizophrenia (dementia præcox) | 27 0 per cent |
| 18 | Paranoia or paranoid conditions | 2 8 per cent |
| *19 | Neuroses (This percentage figure gives no idea of the enormous frequency and importance of the neuroses It is based on the number of neurotic patients admitted to public mental hospitals which constitutes only a small fraction of the total ) | 2 1 per cent |
| 20 | Psychoses with psychopathic personality | |

The history should cover the first awareness of sex, how, when and with what preparedness and attitude evolution of the sex interest, and specific data on sex practice as noted in overt sex activity (physiologic data of erections, emissions or menstruation), as well as the more mental factors of sex fancies and dreams and their effects autoerotic homosexual and heterosexual features attitude to family formation The marital data should include date of marriage, marital adjustment with degree of satisfaction special gratifications and disappointments and difficulties pregnancies and their results attitude to the specific sex factors and satisfactions therefrom contraceptive methods reasons for the method used safety coefficient fear of pregnancy conflicts aroused by the practice

*Personality* —Human personality is so

dominant that its markings may be traced in the pattern of any psychosis, even in an out and out organic one like paresis. Personality in any individual at a given moment in his life is in one sense the condensed record of everything that has gone before in his life, his reaction thereto and the influence of his ancestral heritage. When it is remembered that the personality is made up of intelligence, instinctive drives, interests and hobbies, vocational aptitude and inaptitudes, mood, output of energy, social adaptability, *it will be seen at once how important* it is, how significantly it influences the expression of the psychoses and how carefully it must be considered.

The direct examination of the patient consists of the physical and mental examinations. They are scarcely separable, nor may the one be regarded as more important than the other. As a fair index of the truth and importance of this statement, we may cite again the clinical case of a man with intense headache and projectile vomiting, who barely escaped brain operation for want of a mental examination which when made readily disclosed that his symptoms were functional and not organic and due to an underlying emotional conflict. Conversely an error in diagnosis may easily follow the attempt to puzzle out the significance of somewhat atypical mental symptoms, the meaning of which is at once shown to be paresis if the blood and spinal fluid are carefully examined.

The physical examination consists of a general physical examination, the neurologic examination, the examination of the endocrine organs and the vegetative nervous system, laboratory examination and such contributory and special examinations as may be indicated. Without explanation it is obvious how diagnostically revealing are these examinations.

*Mental Examination*.—A mental examination is not difficult to make. A few suggestions might be helpful. (1) The examiner should not rush into questioning the patient, who should be encouraged to tell his story in his own way. (2) Friendly contact should be established with the patient. (3) Observations should be thorough. (4) Particular attention should be given to so called unco-operative phases of psychosis. (5) Throughout the examination, it should be constantly kept in mind that its purpose is not merely to record symptoms objectively but to interpret mechanisms that underly symptoms. (6) Record examination adequately.

The mental examination may be divided into the examinations of (1) General appearance and behavior, (2) stream of talk and activity, (3) mood (emotion, affect), (4) content and special preoccupations, (5) sensorium and intellectual resources, (6) insight, (7) special examinations.

While formal routine mental examinations are to be deplored, yet the examination when completed should reveal information covering all its divisions. Under each heading there will be found a list of symptoms and signs, some of which will be found in each case.

*I General Appearance and Behavior*.—Here, observation is the chief resource of the examiner. Without asking many questions he should note the general appearance of the patient, the facial expression, posture, the condition of the hair and clothes, the motor activity, whether it is quick or slow, purposeful and related to the environment or aimless and seemingly unrelated. Various important symptoms, including catalepsy, catatonia, cerea flexibilitas, compulsive and impulsive acts, distractibility, echopraxia, mannerisms, mutism, negativism, obsessional behavior, retardation, suggestibility, stupor.

*II Stream of Talk and Activity*.—This is the examination in a general way of the ever flowing stream of mental activity. There is indicated the speed and relations of the thought processes. Some of the following symptoms are likely to be observed: *Dissociation*, distractibility, echolalia, flight of ideas, garrulousness, incoherence, irrelevancy, mutism, neologistic formation, rambling, retarded speech, scattering, sound association, stereotypy, verbigeration, volubility.

*III Mood* (*Emotion, Affect*).—This is the most important part of the mental examination, since both in normal and abnormal mental life the stream of mental activity is given strength, direction and purpose by the emotions. An idea of the emotional reaction may be obtained from

A ORGANIC PSYCHOSES

| | | |
|---|---|---|
| 1 | Traumatic psychoses | 0 3 per cent |
| 2 | Senile psychoses | 12 1 per cent |
| *3 | Psychoses with cerebral arteriosclerosis | 6 4 per cent |
| *4 | General paralysis (paresis) | 10 6 per cent |
| 5 | Psychosis with cerebral syphilis | |
| 6 | Psychoses with Huntington s chorea | 1 2 per cent |
| 7 | Psycho is with brain tumor | |
| 8 | Psychoses with other brain or nervous diseases (Cerebral embolism paralysis agitans meningitis tubercular or other forms multiple sclerosis tables dorsalis acute chorea encephalitis lethargica and other neurologic diseases ) | |
| *9 | Epileptic psychoses | 2 7 per cent |
| 10 | Psychoses with mental deficiency | 3 3 per cent |

B TOXIC PSYCHOSES

| | | |
|---|---|---|
| 11 | Alcoholic psychoses (This figure based on comparative admissions to the State hospitals in the United States in 1920 In 1922–1923 of 4444 consecutive admi sions to the Psychopathic Wards of the Philadelphia Hospital 10 8 per cent had alcoholic psychoses ) | 2 2 per cent |
| 12 | Psychoses due to drugs and other exogenous toxins | 1 1 per cent |
| 13 | Psychoses with pellagra | 0 37 per cent |
| *14 | Psychoses with other somatic diseases (Including delirium with infectious disease postfectious psychosis exhaustion delirium delirium of unknown origin cardio-renal disease diseases of the ductless glands epi demic encephalitis other diseases or conditions ) The percentage figure is undoubtedly too low It is based on admissions to public mental hospitals The majority of these psychoses are encountered in general hospitals in sanitoria and in private practice | 2 81 per cent |

C FUNCTIONAL (PSYCHOGENIC) PSYCHOSES

| | | |
|---|---|---|
| *15 | Manic depressive psychoses | 16 0 per cent |
| *16 | Involutional melancholia | 3 2 per cent |
| *17 | Schizophrenia (dementia præcox) | 27 0 per cent |
| 18 | Paranoia or paranoid conditions | 2 8 per cent |
| *19 | Neuroses (This percentage figure gives no idea of the enormous frequency and importance of the neuroses It is based on the number of neurotic patients admitted to public mental hospitals which constitutes only a small fraction of the total ) | 2 1 per cent |
| 20 | Psychoses with psychopathic personality | |

The history should cover the first awareness of sex, how, when and with what preparedness and attitude evolution of the sex interest and specific data on sex pace as noted in overt sex activity (physiologic data of erections, emissions or menstruation) as well as the more mental factors of sex fancies and dreams and their effects autoerotic, homosexual and heterosexual features, attitude to family formation The marital data should include date of marriage marital adjustment with degree of satisfaction special gratifications and disappointments and difficulties pregnancies and their results attitude to the specific sex factors and satisfactions therefrom contraceptive methods reasons for the method used safety coefficient fear of pregnancy conflicts aroused by the practice

*Personality* —Human personality is so

symptom variations influenced by the previous makeup of the patient yet the constant and dominant etiologic factor is the pathologic alteration in brain structure The symptoms are deteriorative and usually involve regression in the intellectual emotional and ethical fields In all these psychoses the patients are disoriented and reveal defects in memory attention and grasp In the functional psychoses on the other hand the sensorium is usually clear and the intelligence well preserved In the organic psychoses there are generally definite physical and neurologic signs the prognosis is poor but often the preventive opportunities are brilliant

## PARESIS

*Etiology* —The most notable example of an organic psychosis is paresis As is well known it is always due to invasion of the brain by the Treponema pallidum which may be demonstrated in the brain tissue

Only a relatively small proportion of luetics become paretic and therefore the nature of the secondary precipitating factor is an important and moot question On the one hand there must be considered a nervous strain of the specific organism on the other the effect of exogenous stress such as alcohol head trauma and indeed a whole group of damaging physical and emotional agents Since lues is more common in the male and also since it appears from ten to twenty years after the initial infection paresis is obviously more frequent in men It reaches its incidence peak in the fifth decade of life Juvenile paresis appears before the twentieth year (For detailed discussion of Paresis *see* p 1401)

## SENILE PSYCHOSIS

*Etiology* —Brain destruction conditioned by cerebral arteriosclerosis and other factors including old age and possibly by toxic and hereditarial influences The greatest incidence is between the ages of sixty and seventy five years Meggendorfer finds a familial tendency and believes that alcoholism favors early development

*Pathology* —Small brain narrow convolutions thick pia arachnoid fluid filled sulci tortuous and sclerotic vessels and microscopically ganglion cell loss and atrophy glial increase thick prominent vessels cortical fat excess and in the cortex and basal ganglia the presence of typical senile plaques

*Symptoms* —The student may advantageously regard the senile psychoses from three symptomatic angles The first is closely connected with the restrictions and limitations of old age Here we may expect irritability deterioration of normal emotional reactions obstinacy stubbornness self-centering of interests selfishness outbreaks of temper moral laxities or penuriousness The second is somewhat more closely connected with the brain pathology and embraces defects of orientation lessened mental capacity defective attention concentration and thinking a tendency to reminisce and fabricate and finally the keynote symptoms upon which the other phenomena are to a certain extent dependent namely *the failure of recent memory* Far less important in the clinical picture are the symptoms that are in some degree at least influenced by the personality Here we may consider the following subdivisions

(a) *Simple Deterioration* —Defective retention and memory reduced intellectual capacity narrowed interests Often there is suspiciousness irritability and restlessness usually nocturnal

(b) *Presbyophrenic Type* —Marked memory and retention defect with complete disorientation The patient is mentally alert attentive and able to grasp immediate impressions Forgetfulness leads to absurd contradictions and repetitions Prominent are suggestibility and fabrication

(c) *Delirious and Confused Types* —In the early stages there may be deep confusion or delirium

(d) *Depressed and Agitated Types* —Mental deterioration plus pronounced depression and persistent agitation

(e) *Paranoid Types* —Mental deterioration plus persecutory or expansive delusional trends

(f) *Presenile Type* (*Alzheimer s Disease*) —Profound dementia occurring as early as the fortieth year accompanied by aphasia apraxia and often an irritable or anxiou

close observation of the physical expression patterns and by questioning It is important to determine whether or not the emotional life is in keeping with the trend of thought

The psychotic patient may reverberate to any note in the emotional scale and here are listed only a few significant reactions euphoric exhilarated exhalted, depressed anxious, apprehensive suspicious perplexed irritable, furious, silly, indifferent dull apathetic

*II Content and Special Preoccupations* — In this division of the mental examination the examiner is concerned with the identification and study of such phenomena as illusions hallucinations delusions, autistic thinking obsessions, ideas of reference, symbolizations

*I Sensorium and Intellectual Resources* — The binding threads which maintain an appreciation of our relations in the environment to time place and person are readily loosened and even broken In fatigue, in sleep and in anesthesia in many mental disturbances acute mania profound depression in some of the organic reactions like the senile psychoses and, perhaps particularly in the toxic reactions like the deliria we may witness suspensions and even abolitions of conscious awareness of our temporal, spatial and personal connection with the environment The special symptom of inability to be aware of our environmental relations is called disorientation

Other mental functions tested under this heading are memory, remote intermediate and recent, retention and recall counting and calculation reading and recall writing attention school general and current knowledge

*II Insight* —The capacity of the patient to understand his psychosis and its symptoms It is important to record the degree and character of the insight

*III Special Examinations* —In given cases such special examinations as psychometric word association, hypnosis and dream analysis may be indicated

*Mental Mechanisms* —Psychiatry has passed beyond the descriptive phase This phase reached its culmination in Emil Kraepelin whose descriptive observations were so accurate that they have become classical But today just as the internist is not content with hearing a curious sound which signifies aortic regurgitation, unless he can understand the mechanics of the sound so likewise is the psychiatrist not satisfied with the knowledge of the fact that a patient has delusions or illusions, but he wants to know why in a given case the false beliefs or the sensory deceptions take this or that form

Interpretative psychiatry attempts to look beneath the surface of mental symptoms and discover their hidden meaning For instance why does a certain schizophrenic hallucinate so vividly and assert that every one is calling him a sexual pervert? Why does another patient stand for hours with arms outstretched in the form of a cross? What is there in the hidden mental lives of these two patients which has determined the shaping of their mental symptoms? In an hysterical amnesia what particular repressed experience is being concealed from conscious memory? In a psychasthenic fear let us say, of feathers is it the purpose of the phobia to keep from everyday thought an even more disagreeable and painful memory? And if so what is that memory? Is the given attack of acute mania during which the patient is markedly exhilarated and seemingly without a care in the world merely a pathologic compensation for conditions of life that the patient could no longer tolerate? The psychiatrist wishes to penetrate the concealed objective of these phenomena since the more he succeeds in unraveling their genesis the greater are his chances of helping the patient

## THE ORGANIC PSYCHOSES

1 General paralysis (paresis)
2 Senile psychoses
3 Psychoses with cerebral arteriosclerosis
4 Epileptic psychoses
5 Psychoses with mental deficiency
6 Psychoses with cerebral syphilis Huntington s chorea brain tumor encephalitis and other brain and nervous diseases
7 Traumatic psychoses

In this group there are a group of psychoses in which although there are wide

symptom variations influenced by the previous makeup of the patient yet the constant and dominant etiologic factor is the pathologic alteration in brain structure The symptoms are deteriorative and usually involve regression in the intellectual emotional and ethical fields In all these psychoses the patients are disoriented and reveal defects in memory attention and grasp In the functional psychoses on the other hand the sensorium is usually clear and the intelligence well preserved In the organic psychoses there are generally definite physical and neurologic signs the prognosis is poor but often the preventive opportunities are brilliant

## PARESIS

*Etiology* — The most notable example of an organic psychosis is paresis As is well known it is always due to invasion of the brain by the Treponema pallidum which may be demonstrated in the brain tissue

Only a relatively small proportion of luetics become paretic and therefore the nature of the secondary precipitating factor is an important and moot question On the one hand there must be considered a nervous strain of the specific organism on the other the effect of exogenous stress such as alcohol head trauma and indeed a whole group of damaging physical and emotional agents Since lues is more common in the male and also since it appears from ten to twenty years after the initial infection, paresis is obviously more frequent in men It reaches its incidence peak in the fifth decade of life Juvenile paresis appears before the twentieth year (For detailed discussion of Paresis *see* p 1461 )

## SENILE PSYCHOSIS

*Etiology* — Brain destruction conditioned by cerebral arteriosclerosis and other factors including old age and possibly by toxic and *hereditarial influences* The greatest incidence is between the ages of sixty and seventy five years Meggendorfer finds a familial tendency and believes that alcoholism favors early development

*Pathology* — Small brain narrow convolutions thick pia arachnoid fluid filled sulci tortuous and sclerotic vessels and microscopically ganglion cell loss and atrophy, glial increase thick prominent vessels cortical fat excess and in the cortex and basal ganglia the presence of typical senile plaques

*Symptoms* — The student may advantageously regard the senile psychoses from three symptomatic angles The first is closely connected with the restrictions and limitations of old age Here we may expect irritability deterioration of normal emotional reactions obstinacy stubbornness self-centering of interests selfishness outbreaks of temper moral laxities or penuriousness The second is somewhat more closely connected with the brain pathology and embraces defects of orientation lessened mental capacity defective attention concentration and thinking a tendency to reminisce and fabricate, and finally the keynote symptoms upon which the other phenomena are to a certain extent dependent namely *the failure of recent memory* Far less important in the clinical picture are the symptoms that are in some *degree at least influenced by the personality* Here we may consider the following subdivisions

(*a*) *Simple Deterioration* — Defective retention and memory reduced intellectual capacity narrowed interests Often there is suspiciousness irritability and restlessness usually nocturnal

(*b*) *Presbyophrenic Type* — Marked memory and retention defect with complete disorientation The patient is mentally alert attentive and able to grasp immediate impressions Forgetfulness leads to absurd contradictions and repetitions Prominent are suggestibility and fabrication

(*c*) *Delirious and Confused Types* — In the early stages there may be deep confusion or delirium

(*d*) *Depressed and Agitated Types* — Mental deterioration plus pronounced depression and persistent agitation

(*e*) *Paranoid Types* — Mental deterioration plus persecutory or expansive delusional trends

(*f*) *Presenile Type* (*Alzheimer s Disease*) — Profound dementia occurring as early as the fortieth year accompanied by aphasia apraxia and often an irritable or anxiou

depressive mood Pick's disease and other presenile deteriorations may occur

*Course and Prognosis* —There is apt to be a prodromal period of several months duration during which the patient is irritable, sleeps poorly, complains of malaise, muscular weakness and anorexia and becomes seclusive The patient wanders aimlessly about and may lose his way Then appear the typical defect and deterioration symptoms, involving all the intellectual, emotional and ethical faculties and notably the recent memory, the psychopathologic phenomena of old age and perhaps the type symptoms like presbyophrenia delirium and confusion depression and agitation or paranoid reactions

The signs of senility and physical decay are obvious

The course is essentially chronic and progressive and the outlook absolutely unfavorable

*Treatment* —Early recognition attains great importance in view of the fact that the senile dement is readily victimized by designing individuals and thus may bring disgrace to his family and waste his resources

The patient should be protected from the consequences of his psychotic behavior To be kept in mind are the liability of physical injury of sexual offenses or of disgraceful marriages Pyromanic proclivities or simply memory losses may result in serious burns and loss of property Suicide is frequent An easily digested diet warm clothing and measures against constipation must be provided Insomnia may be controlled by mild hydrotherapy and simple hypnotics Often a mental hospital is the wisest solution, not only for the patient but to relieve the distress of the family

## PSYCHOSES WITH CEREBRAL ARTERIOSCLEROSIS

Finer differentiations between senile and arteriosclerotic psychoses which may be demonstrated at the autopsy table and under the eyepiece of the microscope usually fall by the wayside when subjected to the cruder and more practical test of clinical practice Pathologically there are in the brain more areas of softening and not the typical finding of the senile brain—the senile plaque Arteriosclerotic psychoses tend to begin earlier in life Peripheral blood pressure helps little in differential diagnosis, it may be and often is low Perhaps in the arteriosclerotic psychoses attacks of irritability and violent anger are more frequent and severe than in pathologic senility A crude but fairly accurate clinical diagnostic guide is contained in the statement, 'Refrain from a diagnosis of arteriosclerotic brain disease unless there is evidence of general (headache, dizziness fainting attacks) or focal (aphasia, paralyses) brain damage ' (Strecker)

## EPILEPTIC PSYCHOSES

Epilepsy the historical and "sacred disease, ' is still a puzzle to science Even the very questionable diagnosis of idiopathic epilepsy is certainly not permissible unless the epilepsies of gross brain disease (paresis, cerebral lues), toxic and infectious epilepsies (uremia diabetes) and borderline condition epilepsies usually due to endocrine dysfunction are excluded Not only because of the undesirable associations that have gathered around the designation epilepsy but also because of the finer differentiations permitted by the extension of our knowledge, it is better to use the designation ' convulsive disorders " Electroencephalography, even in the present early stages of its development is definitely helpful in establishing the diagnosis and fairly typical brain wave graphs are obtained

Psychiatry is chiefly interested in the mental symptoms that occur in the course of epilepsy and in the personality of the epileptic

*Etiology and Pathology* —The actual cause of epilepsy probably revolves around those conditions which increase the sensitivity of the cortical platform to reaction The stock is usually badly tainted and Gowers states that 76 per cent occurs before the age of twenty years Various pathologic alterations in Ammon s horn in the Pacchionian bodies or edemas have been described (Lennox Cobb Winkleman) One also finds surface gliosis of the hemispheres syphilis arteriosclerosis, arrested develop-

ment and toxic manifestations The difficulty is that usually at autopsy the picture is clouded by the result of the repeated terrific onslaughts of the seizures upon the brain

*Mental Symptoms*.—There is scarcely a specific mental reaction in epilepsy and the diagnosis usually must wait upon the demonstration of the typical seizure or unquestioned petit mal Mentally the traditional irritability may assume such proportions that it is really psychotic, epileptic dream or twilight states with considerable confusion delirious confusion with an ecstatic hallucinatory delusional state or anxiety "conscious delirium" (epileptic fugue state) which has considerable medico legal import, since murder or sex crimes may be committed during the aimless journeys which the epileptic takes and of which he has not the slightest remembrance epileptic furor states following seizures during which the patient becomes maniacal homicidal destructive and a dangerous menace to those about him epileptic equivalent states in which a psychotic episode replaces the seizure, paranoid states in which the personality suspiciousness is carried to an extreme degree and finally, not only grand mal epilepsy but also petit mal may terminate in profound dementia in which every faculty of the mind is extinguished

While the epileptic may remain relatively normal mentally yet his *personality* is almost always pathologic One or more of the following traits are apt to appear Egotism conceit emotional instability hypochondriasis sickly sentimentality in religion inadaptability to environment, cruelty laziness irascibility impulsiveness excessive sexual tendencies criminalism violent impulses

*Course Prognosis and Treatment*.—Life is somewhat shortened not only as a direct result of the damage of the disease serious injuries status epilepticus secondary pneumonia but also the epileptic is apt to be a sickly individual with various gastro intestinal and skin disturbances The course is chronic and progressive The outlook is somewhat better in childhood

During the attack care should be exercised to protect the tongue teeth and body from injury In every instance the patient constitutes an individual therapeutic challenge Foci of infection should be removed rational surgical procedures should be carried out endocrine dysfunction combated lues and other systemic disease vigorously treated Practically in every patient it is necessary to prevent constipation bring the nutritional and functional activity of the body up to *par* and help to select a suitable, non dangerous and if possible out door occupation The drug of choice is dilantin $4\frac{1}{2}$ to 9 grains daily or if dilantin cannot be tolerated, phenobarbital 1 to 6 grains daily Other useful drugs are mesantoin (0 3 to 1 0 gm daily) mebaral or prominal (30 mgm to 0 2 gm three times daily), and for petit mal tridione (1 to 3 gm daily) With the appearance of definite mental symptoms the protection of a suitable institution should be sought for the patient Epileptics should be advised not to marry

## CONSTITUTIONAL PSYCHOPATHIC INFERIORITY

This is at best an unsatisfactory classification but nevertheless certain types of criminalism emotional instability, inadequate personality, paranoid personality pathologic lying and sexual psychopathy correspond rather closely to the conception which prompted the designation, constitutional psychopathic inferiority There is an obvious defect consisting of an apparent constitutional lack of responsiveness to the social demands of honesty or truthfulness or decency or consideration for others which incapacitates the patient from settling down to any permanent standardized activity The individual is therefore emotionally unstable is not to be depended upon, acts on impulses shows poor judgement and is constantly led into unwise activities the consequence of which he is able to realize intellectually but not evaluate Since one cannot explain or trace the abnormal behavior of these individuals to any definite disease or organic process the conclusion is justifiable at present that there is always some constitutional lack of endowment in each case and for purposes of classification the group is termed constitutional inferior

to which the word psychopathic is added to signify the marked instability and lack of the social responsiveness

The social and educational problems of this class of patients are of paramount importance The relationship of this group *to such problems* as prostitution venereal disease vagrancy delinquency illegitimacy alcoholism and drug addiction constitutes an active need for thorough research and the dissemination of knowledge throughout every community The need for careful supervision and definite measures to safeguard society at large from these individuals *should stimulate serious thinking by people* in general Kraepelin indicated the truth of this assertion when he showed that 54 per cent of the men and nearly one-third of the women in this group as a result of their moral deterioration come into contact with the courts on account of threats assaults quarrels and vagrancy

It is probably fair to say that constitutional psychopathic inferiority represents a kind of feeblemindedness which involves all spheres *save the intellectual one* that the inferior is like the low grade defective in that *he fails to profit by experience*

## THE TOXIC PSYCHOSES

Within the domain of the toxic psychoses is embraced a vast amount of clinical territory Much of this is directly included in the province of the general practice There is at once suggested a natural etiologic division *(a) into those* psychoses primarily due to the ingestion of toxic agents into the body as in the instances of alcohol and opium *(b)* those psychoses *influenced* by *autointoxications* within the body as in any infectious disease, or in even more direct intoxications like uremia in chronic infections *like* tuberculosis in such deficiency diseases as pellagra, in decompensating heart disease in the disturbances of metabolism occasioned by endocrine disorders In the last analysis *it is important to remember that every organic disease has its mental as well as its somatic components* Generally speaking the etiology of the toxic psychoses is usually clear whether it be on an exogenous or an endogenous basis the physical findings are those of the disease in question with a fairly constant background of fever leukocytosis and weight loss and in the skin kidneys *gastro intestinal tract,* and vasomotor and sympathetic systems, the usual accompaniments of fever or toxemia or both The prognosis is good

While the student must expect wide departure particularly in degree yet the mental paradigm of the toxic psychoses is *delirium* which in its pure expression includes clouding of the consciousness motor restlessness, hallucinosis apprehension and emotional instability

*Even more important than the therapy* of each individual toxic psychotic reaction are the highly important general principles of treatment (1) a large intake of fluid by mouth and if necessary subcutaneous colonic or intravenous administrations excepting in instances where there is brain edema (2) limitation of narcotics which are customarily used entirely too freely in the treatment of the toxic psychoses (in this connection it is suggested that the physician *have in mind the toxicity and the elimination* time of the hypnotic drugs he employs) (3) treatment of the usual accompanying constipation (4) hydrotherapy (5) *free* elimination (6) removal of poisons and infections including focal infection (7) dietetic and tonic treatment (8) protection of the patient against danger to himself and others

### Exogenous Toxic Psychoses

Obviously not all the mental *reactions* caused by poisons which may be deliberately *or accidentally taken into the body* can be described

The effect of *alcohol* which is unquestionably *toxic to the nervous system furnishes* a fair clinical example of the result of other serious poisons It is always narcotic it lessens motor activity increases *reflexes* diminishes physical strength lowers the fatigue point interferes with clarity of ideation impairs judgment and work capacity impairs memory and emotional stability and finally produces the debacle of complete intellectual emotional and ethical deterioration (*See* Chapter 12)

The student must not be too ready to diagnose alcoholic psychosis Alcoholism may be a symptom of paresis manic-depressive dementia praecox or epilepsy

*Opium* and its derivatives particularly *morphine* are frequently the resort of the psychopath when faced with even the low hurdles of life Their habitual use involves a profound deterioration of the ethics of the individual This is strongly marked in his efforts to obtain the drug

*Cocaine* is chiefly the drug of the underworld where it is often utilized by the criminal to pep up his courage for the commission of a crime and also to some extent it is dabbled in by a certain irresponsible stratum of so-called ' society The prolonged use of either morphine or cocaine as in the instance of alcohol finally deteriorates the taker to a low intellectual emotional and moral level

The efforts to combat cocaine addiction have been relatively successful and its incidence is now comparatively low On the other hand the use of an equally dangerous drug marihuana has increased

The symptoms of a psychosis with *Marihuana* vary depending upon the basic personality Agitation a loss of time relationships visual hallucinations of a sexual character and the complaints of ringing in the ears and dizziness are the most common ones Delusions of persecution ideas of reference flight of ideas and suicidal attempts constitute other features

The list of habit forming drugs is long and includes not only *ether chloroform cannabis indica* but even such milder hypnotics as the *bromides barbiturates* and many others

In the industries psychotic symptoms may be produced by *lead arsenic mercury* and the *gases* and many other industrial poisons (*See* Chapter 13)

### Special Treatment

In the toxic psychoses prophylaxis is almost unlimited Sensible explanatory scientific propaganda should lessen the incidence of psychotic reactions due to habit forming drugs protection and personal hygiene should make large inroads into the mental morbidity of the industrial poisons proper diet better control of infectious diseases and adequate periods of convalescence should reduce the mental pathology incident to metabolic disturbances and infectious diseases

The therapy of any exogenous toxic psychosis may be summed up under withdrawal free elimination hydrotherapy dietetic and reeducative measures Emergency methods in severe delirium tremens must be kept in mind (*See* Chapter 12)

## PSYCHOSES WITH SOMATIC DISEASE

Probably the largest field for psychiatry in the practice of medicine is in the psychotic reactions coincident with the fever and toxemia of infectious diseases with exhaustion with metabolic and deficiency diseases with cardiorenal disease and in short with every known pathologic condition There is no dividing line The patient with uncomplicated lobar pneumonia may in a few hours become delirious and consequently a problem in psychiatry The patient who is convalescing from influenza may suddenly become depressed and suicidal The patient with cardiac failure may rapidly become irritable suspicious confused and delusional Every somatic disease has clinically a mental as well as a physical expression which are interrelated

If the student keeps in mind the delirium paradigm—motor excitement incoherence hallucinosis disorientation deep confusion or at least some degree of clouding of consciousness then the psychiatric diagnostic problem becomes surprisingly simple Naturally variations in degree and departures will be encountered so that he may expect to find the framework of delirium filled in by such phenomena as convulsions catatonia stupor fear depression with suicidal attempts euphoria irritability suspiciousness delusional formation (usually transitory) dulness apathy coma or neurasthenic symptoms Likewise if the general therapeutic principles that have been stressed together with the specific therapy of the basic disease are kept in mind then the problems of treatment are usually not difficult and the results are highly gratifying

## MANIC-DEPRESSIVE PSYCHOSIS

*Definition*.—A recoverable but persistently recurrent type of mental disease second only to schizophrenia in importance and statistical frequency and marked by wide swings in mood and psychomotor reactions.

*Etiology*.—Unquestionably there are chemical, metabolic and organic factors at work in the genesis of this psychosis but they are still too little understood and too inconstant to be dignified into a specific etiologic role. Many years ago Kraepelin indicated the distortion of personality—the prepsychotic makeup—when he observed that among those who developed frank manic-depressive reactions, 12.1 per cent had manifested previously a depressive makeup, 9 per cent manic, 12.4 per cent were "irascible" and "nervous," 3 to 4 per cent, cyclothymic. More profitable etiologically than rigid neuropathologic interpretations is earnest attention to the "constitutional basis," which has its roots in heredity. This basis has physical as well as psychologic components and in its pure type we may think of an individual of the pyknic type, heavy, broad and thick set, who is an extrovert.

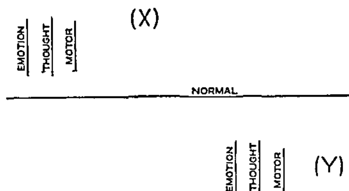

Fig. 235

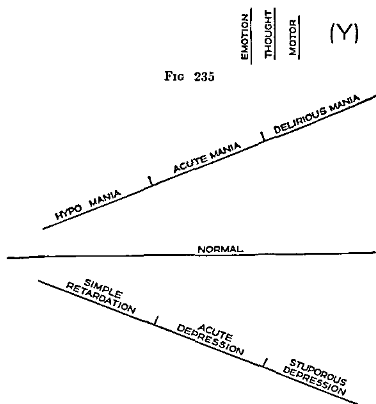

Fig. 236

Figs. 235 and 236.—Illustrating variations in the intensity of the symptoms in manic-depressive psychosis. ("Clinical Psychiatry," by Strecker and Ebaugh, courtesy of P. Blakiston's Son & Co., 1917.)

An extrovert is predominantly a man of action He "wastes" little time on reflective thinking accomplishes much routine work and is often effective and executive He expresses himself readily and positively Concerning questions issues policies beliefs he is apt to be very strongly *pro* or *con* but often his feelings are transitory His decisions are frequently of the "hair trigger" type He is a loyal enthusiastic friend and a bitter enemy but does not hold resentments for a long time and readily forgives He is energetic cheerful and sociable This type of personality does not necessarily spell manic-depressive but if the psychosis does occur it is often engrafted on similar dispositional traits

As precipitating causes one must consider psychogenic and somatic strain and stress and destructive influences traceable to faulty training and environment The psychosis is said to be more common among flight of ideas as evidenced by speech and also will be in a state of more or less marked physical or motor activity In acute melancholia the reverse is true This clinical point of view, usual parallelism between the unit symptoms and the chief degrees of severity of the psychosis is expressed in the following diagrams

There are numerous mixed states in which the unit symptoms referred to emotion, thought and motor activity are not in accord The chief forms are represented in the diagram opposite by the simple expedient of transposing the unit symptoms above and below a normal level line Thus maniacal stupor clinically consists of emotional exaltation slowing of thought and decreased motor activity

Since manic-depressive tends to recur throughout the life of the patient, one must expect many variations Only a few are given

| *Maniacal stupor* | *Agitated depression* | *Unproductive mania* | *Depressive mania* | *Depression with flight* | *Akinetic mania* | |
|---|---|---|---|---|---|---|
| E | I M | E M | M | I | E I | |
| I M | E | I | E I | E M | M | Normal |

females and is apt to be manifested before the twenty fifth year is more prevalent in urban than in rural areas and occurs with great freqeuncy in Jews and in Negroes

*Symptoms* —Waiving strict scientific accuracy for the sake of clarity, the student will probably get a workable conception of clinical manic depressive if he fixes his mind on the three functions which are chiefly affected—emotion (E), ideation (I), motor activity (M) — and pictures them either above or below a theoretical normal line according to the presenting phase of mania or depression Thus in classical or acute mania the emotions (affect mood) the ideation (activity of thought) and the motor behavior all present themselves to the observer as definitely increased or raised well above a normal average there being a more or less close agreement or parallelism between the individual unit symptoms Commonly the patient who is exhilarated or mercurial as to mood will likewise exhibit a corresponding degree of distractibility and

Viewed from an objective *psychologic* platform the patient in the manic phase of the psychosis is apparently without restraint and is seemingly unhampered by any counterbalance or inhibition in his emotional thought and motor expression the depressive seems bound in the chains of emotional depression thought and motor retardation This has led McDougal to regard the two contrasting phases of the diseases as the unchecked manifestation of the self-assertive and self submissive instincts respectively A more total point of view might consider the depressive phase as a temporary withdrawal in the face of defeat in the management of ego sex or (and) herd problems and the manic phase likewise a withdrawal and defeat which is psychologically camouflaged and prevented from reaching too clear a conscious realization by the unimpeded flow of energy in all directions emotionally ideationally and in the output of muscle energy Freud makes an analogy between depression and normal grief In normal

mourning the lost love object is identified in consciousness and thus the path is left open to a cessation of grief and the finding of new love attachments in pathologic depression the path in consciousness is blocked The psychoanalytic school explains depression with its guilt feelings on the basis of the lashing out of the super ego (the self-critique and ethical censor) against the defenseless ego

1 *General* —Disturbed sleep impaired nutrition (in mania) These symptoms are intensified in hyperacute mania, and fever with delirium like manifestations is often added Insomnia loss of weight coated tongue, sallow skin marked constipation (in depression)

2 *Body Systems* —Overactive heart, increased output of urine heightened metabolism (in mania) Cardiac activity weakened decreased urine output depressed metabolism Gastric achylia is not uncommon (in depression)

3 *Subjective Sensations* —Many varieties often associated with somatic delusions In depression there are complaints of numbness paresthesias dizziness ringing in ears

4 *Neurologic* —No constant findings but usually there are some disturbances In severe grades of mania there may be marked exaggeration of tendon reflexes and muscle tremor

TABLE 67

|---|---|
| *Attitude and General Behavior* | |
| *Euphoria exhilaration* and *rapid shift* of emotional range (irritability impatience anger rage) to be noted in facies posture dress general behavior | *Depression* and *retardation* In mixed and stuporous reactions one may encounter various catatonic reactions (catalepsy cerea) |
| Stream of Mental Activity and Speech | |
| *Distractibility* volubility *flight of ideas* rhyming sound association | *Poverty of thought mutism* |
| Affect and Mood | |
| All degrees of *euphoria exhilaration* irritability *mercurial like alterations of mood* | Range from feelings of *inadequacy* and subjective lack of interest to *acute mental agony* Suicidal attempts Stupor |
| Mental Trend Content of Thought | |
| Inconstant shifting and often grandiose *delusions* | More tenacious *delusions* of wrong doing self accusation hypochondriacal somatic |
| Paranoid trends ideas of reference and influence persecutory delusions—all may occur | |
| Hallucinations rare but do occur in very severe manic states and in stuporous phases | |
| Illusions | Illusions |
| Sensorium Mental Grasp and Capacity | |
| Excepting briefly or in severe grades of excitement and depression the sensorium memory attention capacity orientation retention and recall counting and calculation reading and recall school general and current knowledge are not intrinsically disturbed The manic patient is apt to cover page after page with hurried lengthy untidy profusely capitalized underscored and crudely illustrated communications | |
| Insight | |
| During the attack especially in mania insight is at best quite faulty though rarely completely absent | |

*Mental and Physical Symptoms* —In listed form the sypmtoms are given in Table 67 the more prominent ones being italicized

*Physical Summary* —The absence of a specific pathognomonic syndrome does not imply that organic morbidity is insignificant or absent If the examination has been intensive and thorough *it will discover in the majority of instances somatic disturbances which at least indirectly are related to the psychosis* and which demand careful attention In addition the following phenomena have been reported by various observers

5 *Laboratory* —While there are no specific criteria there may be albuminuria and other pathologic urinary findings diminished or absent hydrochloric acid disturbances in blood chemistry A high basal metabolic rate has been repeatedly reported There may be a leukocytic increase in mania especially at the beginning of the phase in some cases a temperature and pulse rate rise during mania and again particularly in its inception a definite erythrocyte increase during the transition from normality to either excitement or depression and a fall under reverse conditions *i e* transition back to normality and blood pressure is higher both in mania and in melancholia than in quiescence

*Prognosis* —Manic phases seem to be somewhat more common than depressions Kraepelin stated that the first attack is a depression in 60 to 70 per cent of patients two-thirds of the melancholias are followed by remission and one third by mania and then a remission when mania is the first manifestation two thirds of the cases are likewise followed by remission Recovery from the single attack is the rule and the duration of the illness ranges from a few days to several months or longer Future attacks are often a repetition of the initial one although the tendency is toward greater frequency and severity The outlook seems to be better in proportion to the seriousness of the precipitating situation (so-called reactive types) the soundness of the heredity and the personality It is somewhat doubtful if any valid index of prognosis can be taken from the psychotic content though it has been stated that gross somatic and nihilistic delusions are unfavorable Mental deterioration is exceptional and may usually be explained by the addition of a complicating factor such as arteriosclerosis

*Treatment* – Given a strong constitutional basis sensible *preventive* measures should be set into motion early in childhood and proper training should be followed by some effort to modify the more destructive conditions of life In a large percentage of cases the attack itself must be dealt with in a suitable mental hospital or sanatorium From the somatic aspect each patient is a problem in internal medicine and any pathologic finding,—whether it be tuberculosis heart or kidney endocrine dysfunction gastrointestinal disturbance colonic stasis or *actual* foci of infection—must be dealt with unhesitatingly and intensively General measures of treatment are of the utmost importance The nutrition should be kept at the highest possible point and in some cases nasal feeding is unavoidable rest and often rest in bed particularly for depressed patients is helpful and hydrotherapy including the prolonged neutral bath is a valuable adjunct far superior to hypnotic overdrugging the patient should be protected against the well meant but usually harmful effect of many visitors With kindness sympathy tact and firmness the physician must manage the patient and attempt to direct his perverted energies into useful channels If the patient is at all accessible he should be frequently encouraged to talk things over with the physician

The greatest dangers inherent in the manic-depressive psychosis are suicide (stemming from the depressive phase) and exhaustion (stemming from the manic phase) The great advances in the treatment with convulsive therapy have therefore been truly lifesaving The treatment of choice for both phases is electroshock the best results occur in the depressed patient From nine to twelve convulsions of the grand mal type are usually required for the depressed patient but the manic patient requires fifteen to twenty In our experience the average patient may be expected to recover or improve from his depression within four weeks from the time convulsive shock therapy is started [1] There is no evidence to show that future attacks are prevented by electroshock therapy

Prolonged narcosis for as long as six weeks may be useful for some of the manic reactions the satisfactory drug being sodium amytal Sleep for from twenty to twenty-two hours a day is promoted by slowly increasing the dose of sodium amytal

[1] From Practical Clinical Psychiatry by Strecker Ebaugh and Ewalt 6th Edition Philadelphia The Blakiston Co 1947

mourning the lost love object is identified in consciousness and thus the path is left open to a cessation of grief and the finding of new love attachments in pathologic depression the path in consciousness is blocked The psychoanalytic school explains depression with its guilt feelings on the basis of the lashing out of the super-ego (the self-critique and ethical censor) against the defenseless ego

1 *General* —Disturbed sleep impaired nutrition (in mania) These symptoms are intensified in hyperacute mania and fever with delirium like manifestations is often added Insomnia loss of weight coated tongue, sallow skin, marked constipation (in depression)

2 *Body Systems* —Overactive heart increased output of urine, heightened metabolism (in mania) Cardiac activity weak

| Paranoid trends ideas of reference and influence persecutory delusions—all may occur | |
| Hallucinations rare but do occur in very severe manic states and in stuporous phases | |
| Illusions | Illusions |
| Sensorium Mental Grasp and Capacity | |
| Excepting briefly or in severe grades of excitement and depression the sensorium memory attention capacity orientation retention and recall counting and calculation reading and recall school general and current knowledge are not intrinsically disturbed The manic patient is apt to cover page after page with hurried lengthy untidy profusely capitalized underscored and crudely illustrated communications | |
| Insight | |
| During the attack especially in mania insight is at best quite faulty though rarely completely absent | |

*Mental and Physical Symptoms* – In listed form the symptoms are given in Table 67 the more prominent ones being italicized

*Physical Summary* —The absence of a specific pathognomonic syndrome does not imply that organic morbidity is insignificant or absent If the examination has been intensive and thorough *it will discover in the majority of instances, somatic disturbances which at least indirectly are related to the psychosis* and which demand careful attention In addition the following phenomena have been reported by various observers

ened decreased urine output depressed metabolism Gastric achylia is not uncommon (in depression)

3 *Subjective Sensations* —Many varieties often associated with somatic delusions In depression there are complaints of numbness paresthesias dizziness ringing in ears

4 *Neurologic* —No constant findings but usually there are some disturbances In severe grades of mania there may be marked exaggeration of tendon reflexes and muscle tremor

and it should include extra feedings preferably raw eggs and milk

Long rest periods are advisable Sometimes the prolonged bath induces quiet and sleep It is frequently necessary to employ hypnotic drugs in as small dosage as is possible Paraldehyde bromides and chloral veronal sodium amytal and other barbiturates have all been recommended

Always the patient is a problem in internal medicine Endocrine imbalances disturbances of circulation cardio-renal and gastro-intestinal pathology pelvic disease focal infection may all need vigorous treatment Constipation usually requires hygienic and dietary control massage and other measures Gynecologic consultations are needed not only to determine and treat pelvic pathology but also to obtain expert advice concerning endocrine therapy

In the vast majority of patients sanatorium or hospital care is imperative Infrequent visiting by relatives and friends should be the rule Experience shows they are likely to increase depression anxiety and apprehension

The patients are not always and certainly not throughout the entire course of the psychosis inaccessible to psychotherapeutic efforts Nonargumentative discussions persuasion reassurances suggestions are beneficial and certainly after the psychosis is over they are remembered with gratitude by the patient The nurse should be not merely an efficient robot but should work with the psychiatrist toward the accomplishment of the physical and psychologic adjustment

Occupational therapy is here as in the treatment of many psychoses the important therapeutic adjunct There is a wide range of choice—basketry weaving gardening and modelling

It may be valuable to change the form of occupation from time to time and it should not be so complex and intricate that it overfatigues the already wearied mind of the patient nor should it be so simple that it demands little or no attention and consequently provides no escape from the gloomy subject matter of the psychosis

After recovery the physician often aided by the social worker should supervise the patient and keep a watchful eye on the environment at least until the adjustment has been completed

## SCHIZOPHRENIA (DEMENTIA PRÆCOX)

*Etiology* —If manic-depressive is the psychosis of the extrovert then schizophrenia is strikingly the psychosis of the introvert The organic toxic and endocrine implications of præcox have been investigated by Nissl Mott Josephy Funfgeld Marcuse Kitabayashi Naito and others but thus far the findings while provocative are still too inconstant to justify the assumption of a specific causal relationship Perhaps our etiologic information is contained in the opening sentence of this paragraph

Schizophrenia tends to develop in persons with the shut in (Meyer) seclusive type of personality often on the basis of mental conflicts faulty habit formation and instinctive maladjustments particularly along the lines of sex extending back to early childhood and adolescence

The physical habitus in its pure form is the leptic or light relatively tall slender type The normal psychologic traits are those of the introvert

The introvert is the antithesis of the extrovert He is reserved a deep thinker disinclined to go into action Thought is his powerful weapon He is introspective and analytical At his best he plans thoughtfully for the future and often confers immense benefits upon his fellow men At his worst he is an impractical theorist visionary and dreamer To the world he appears to be distant gloomy cold unfriendly and lacking in strong personal feelings

The etiology of schizophrenia is so complex that in each individual patient there must be a careful evaluation of psychogenic toxic and organic (often endocrine) elements The psychosis frequently manifests itself early in life the largest percentage of cases appearing before the age of twenty five years It is more frequent in males than in females occurs earlier in males is more prevalent in cities than in rural districts is more common in the foreign population and more frequent in negroes than in whites

Prefrontal lobotomy has also been used by many authorities, including Freeman and Watts, though with better results in the chronically depressed and agitated patient than in the manic patient This procedure will be discussed more fully below

## REACTIVE DEPRESSIONS

A very healthy trend in modern psychiatry, thoroughly justified by increased information, is the separating out from the endogenous, constitutional and manic-depressive *depressions, the so called reactive* depressions Generally speaking, the reactive depressions are less dependent upon inner, constitutional factors and more dependent upon environmental circumstances Harrowes feels that the patient becomes depressed because of an etiologic life situation and continues to react to it in the psychosis The usual symptomatic picture is depression, lack of concentration and interest, loss of thought capacity increased *sense of effort, headache and forgetfulness*

The treatment is psychotherapy but since suicide is a real danger in these depressions, electroshock should be seriously considered

## INVOLUTIONAL MELANCHOLIA

Involutional melancholia is probably a mixed form of manic depressive in which the motor retardation is often replaced by restlessness and agitation It occurs more frequently in women than in men the ratio being about 3 to 2 it appears during the fourth and fifth decades of life or even later, heredity is said *to influence the development* of about 60 per cent of cases and the little understood organic and psychic pathology of the climacteric is probably also determining

The mood is depressed and apprehensive there is usually some degree of motor overactivity which may mount to a veritable frenzy of agitated excitement, suicidal attempts are common in about 10 per cent of patients there occur such catatonic phenomena as *fixed* attitudes, catalepsy negativism, stereotypy, grimacing, mannerisms, automatic movements, food refusal impulsive violence, resistiveness, destructiveness, violent scolding, unapproachability, *mutism, retention of urine and feces* often there is poverty of thought with monotonous and repetitive speech, the delusional formation is apt to be along the line of depression, self-accusation, self-depreciation, with hypochondriacal and gross somatic ideas

The organic morbidity is greater than in ordinary manic depressive and one may expect to encounter evidences of precocious senility, insomnia, profound disturbance of *nutrition with anorexia and sometimes* extreme weight loss circulatory, pelvic and digestive symptoms, particularly constipation and a great variety of subjective sensations

The course is quite protracted After a prodromal period of about a year the psychosis may endure for two, three, four or even more years

The prognosis is fairly good with a recovery rate of from 23 to 40 per cent *About 25 to 32 per cent are said to dement* About 20 per cent die within two years and the death-rate by suicide and intercurrent disease is fairly high The outlook is relatively unfavorable after the age of fifty five years or in the presence of advanced senile changes It is generally considered that a rapid gain in weight and general physical improvement constitute hopeful signs

*Treatment* —Every woman should be prepared for the menopause and the traditional ideas concerning its threat to the mind should be vigorously combated The physician should make a careful evaluation of the inherited organic psychic and environ*mental flaws in each patient* From such evaluation will come sensible preventive measures and safeguards

Should the actual psychosis develop suicide is such *a constant threat that tactful* vigilance must never be relaxed The best protection is the understanding and efficient psychiatric nurse

If no contraindications exist the most satisfactory treatment is electroshock therapy (*see* p 1427)

Frequently a gain in weight is the first sign of improvement and recovery The diet must be liberal rich in vitamin content,

statistics misleading. Of the early and mild group probably one fourth recover or at least attain a very satisfactory level of social readjustment. Of the more severe and outspoken symptomatically developed group 7.4 per cent recovered and 40.9 per cent improved definitely in five years or less. Catatonic cases are somewhat more favorable. The prognosis has been bettered by the introduction of the drastic therapies.

*Treatment.*—The social and economic threat of schizophrenia is both quantitatively and qualitatively so grave that every intelligent preventive measure should be instituted. These aspects offer the most brilliant opportunities particularly during the formative period of childhood. There is being delineated with more and more accuracy a personality pattern into which schizophrenia is so easily woven. This personality pattern has rather distinctive mental and even physical features so that it is not so difficult to identify. Children who manifest this type of personality should be made the target of intensive effort. Prevention should be carried out along the lines of attempting to modify this personality variously described as introverted, seclusive, schizoid. The prophylactic objective should be to strive for a more even balance between individual and environment and in some degree to "exteriorize" or socialize him.

For the child the home should be first and foremost a place in which is found an atmosphere of harmony and happiness. There should be neither unduly harsh discipline nor its opposite spoiling. Competition between brothers and sisters in the home for the favor of parents, particularly when spurred on by "playing favorites" by parents, is pernicious. The attempt to stimulate a child by too constantly pointing out the assets in brothers or sisters usually results in the production of inferiority feelings and is a hazardous process. There should be liberal doses of explanation to the child in the parent child relationship and particularly should punishment contain a generous leaven of explanation. Companionship with other children of both sexes, outdoor life, athletics and all reasonable socializing influences should be encouraged. It should be made easy for the child to bring his playmates into the home and there should be no risk that things would be seen or heard there that would shame him before other children. Sex and particularly the concrete facts of sex are always difficult for the potential schizophrenic and therefore effort should be made to prevent phantasy by supplying competent knowledge of sex hygiene and to discourage rumination by always discussing such matters without emotion and with only a modicum of moralization. Sex instruction should be begun comparatively early in childhood but naturally in a degree and in detail suitable to the age of the child.

Children have toward their parents an attitude of idealistic identification. Unconsciously they supplement their own weakness by identifying themselves in the parents. Here is a strong emotional bond leading to indiscriminate imitation and containing sources of danger particularly for the introverted child. The goal of any real psychology of childhood is to obtain for the child a true psychologic maturity. If this is not accomplished the child is destined for a life of slavish imitation of those who become the emotional surrogates for his parents. The parent-child bond must be loosened, not too abruptly but nevertheless surely, and independence of thought and action must be wisely and continuously encouraged.

Introverted children read a great deal and while their reading must not be too rigidly ordered, yet it should in some measure be directed toward types of literature not too luridly and completely phantastic. Religion supplies an important need and it should be a source of beauty and inspiration but social and practical too, and above all not grimly fear producing.

These are but a few of the conceptions that may be advantageously utilized in the attempt to prevent the development of schizophrenia not only in children but even later in life in those ingrowing personalities who are in danger of this chronic maladjustment.

From the standpoint of the treatment of the psychosis itself modern advances both in psychotherapy and pharmacology offer the patient a far better opportunity for

*Symptoms* —Psychologically, the foundation for the host of symptoms appears to be the withdrawal from reality and the dissociation between emotion (affect) and thought The withdrawal is manifested in many schizophrenic reactions and, perhaps, reaches its height in catatonic stupor during which the patient almost completely shuts himself off from contact with the environment Schizophrenia means splitting or dissociation and it too, is strikingly illustrated in many of the psychotic reactions of the patients in whom the emotional reaction apparently is at variance or very inadequate with the accessible content of thought On such a foundation there is erected an elaborate structure of clinical symptoms A summary based on a statistical study of many patients includes the following

1 *General Behavior* —Oddities of many types silliness incongruity stereotypy, mannerisms impulsive outbreaks untidiness marked mental inertia rigidity and attitudinizing

2 *Stream of Activity and Talk* —Autistic thinking dream like ideas feelings of being forced or of interference with the mind from the outside, physical and mythical influences incoherence rambling blocking evasiveness verbigeration, neologisms echolalia echopraxia mutism, negativism catatonia

3 *Mood and Special Preoccupation* —(a) Dissociation of affect inadequate and incoordinate affect ambivalence apathy indifference

(b) *Trend Reactions Topical Reactions Projection* —1 Persecutory ideas feeling of mistreatment food tampered with poisoned 'doped'

2 Ideas of reference—feeling of being talked about people pass remarks that "refer"

3 Ideas of influence — feeling of being hypnotized under mental control mental telepathy, mental spells hypodermic injections, radio machines

4 Hallucinations in various fields auditory hallucinations frequently of a religious pattern on the basis of overcompensation

5 Bizarre somatic sensations and delusions—organs have been removed brain has been removed vagina has been stopped up electric sensations through the body, electric wires connecting with the brain

6 Overcompensation in the form of day dreaming phantasies being God a saint leader of a new religion

7 Unintelligible and unexplainable activity

In the *paranoid* type (25 per cent) delusions particularly of persecution or grandeur, *often fairly well systematized* for a time at least and hallucinations are prominent in the *catatonic* type (10 per cent) there is negativism and conduct peculiarity *with phases of stupor or excitement* marked by impulsive queer, stereotyped behavior and hallucinations, in *hebephrenia* (52 per cent) there is silliness, unexplained smiling laughter grimacing mannerisms and peculiar and changeable ideas which have an absurd and grotesque content, and in the *simple* type *(8 per cent) interest is at a low* ebb there is apathy and strange behavior and delusions and hallucinations are either abortive and fragmentary or absent entirely

The field of *physical* symptomatology has been industriously tilled and although a specific picture cannot be traced many of the findings are strongly suggestive of underlying organic factors with an endocrine basis If such a basis exists it is probably most clearly expressed in the physical habitus described as leptic or asthenic The heart and vascular apparatus are often small Vasomotor sympathetic phenomena such as cyanosis localized sweating, edema, dilated pupils and increase in salivation are fairly common *Tuberculosis is rather* frequent In catatonic cases there is a tendency to show a low metabolic rate Gastro intestinal disturbances undernutrition and extreme constipation are often observed Kasanin reports high sustained sugar curve during stupor and Hertz finds shortening of the blood-coagulation time Somewhat remarkable are the occasional marked improvements following accidental and severe acute infections

*Prognosis* —Variability in diagnostic standards and the difficulty of obtaining accurate information concerning mild early and non institutionalized patients render

statistics misleading Of the early and mild group probably one fourth recover or at least attain a very satisfactory level of social readjustment Of the more severe and outspoken symptomatically developed group 7 4 per cent recovered and 40 9 per cent improved definitely in five years or less Catatonic cases are somewhat more favorable The prognosis has been bettered by the introduction of the drastic therapies

*Treatment* — The social and economic threat of schizophrenia is both quantitatively and qualitatively so grave that every intelligent preventive measure should be instituted These aspects offer the most brilliant opportunities particularly during the formative period of childhood There is being delineated with more and more accuracy a personality pattern into which schizophrenia is so easily woven This personality pattern has rather distinctive mental and even physical features so that it is not so difficult to identify Children who manifest this type of personality should be made the target of intensive effort Prevention should be carried out along the lines of attempting to modify this personality variously described as 'introverted' seclusive schizoid The prophylactic objective should be to strive for a more even balance between individual and environment and in some degree to exteriorize or socialize him

Children have toward their parents an attitude of idealistic identification Unconsciously they supplement their own weakness by identifying themselves in the parents Here is a strong emotional bond leading to indiscriminate imitation and containing sources of danger particularly for the introverted child The goal of any real psychology of childhood is to obtain for the child a true psychologic maturity If this is not accomplished the child is destined for a life of lavish imitation of those who become the emotional surrogates for his parents The parent-child bond must be loosened not too abruptly but nevertheless surely and independence of thought and action must be wisely and continuously encouraged

Introverted children read a great deal and while their reading must not be too rigidly ordered yet it should in some measure be directed toward types of literature not too luridly and completely phantastic Religion supplies an important need and it should be a source of beauty and inspiration but social and practical too and above all not grimly fear producing

These are but a few of the conceptions that may be advantageously utilized in the attempt to prevent the development of schizophrenia not only in children but even later in life in those ingrowing personalities who are in danger of this chronic maladjustment

From the standpoint of the treatment of the psychosis itself modern advances both in psychotherapy and pharmacology offer the patient a far better opportunity for

marked improvement and even recovery than ever before

Insulin-hypoglycemic therapy is the treatment of choice in schizophrenia. The best results are obtained in cases of recent origin (under six months). Other somatic methods for schizophrenia include electroshock, combined insulin and electroshock, prolonged narcosis, electronarcosis, and prefrontal lobotomy.

The psychotherapy of schizophrenia is often fruitful when the patient is scrutinized in the long section of his life history according to the psychobiologic formula of Adolf Meyer. It brings to the fore such pertinent and therapeutically stimulating questions as "What are the resources of the patient? What has he to react with? What is the situation in life he is called on to meet? Can we modify his resources in order to enable him better to meet the situation or can we modify the situation so that he may better meet it with his resources?

There is much difference of opinion concerning the therapeutic application of psychoanalysis. Zilboorg advises so called "affective reintegration." It seems obvious that psychoanalysis must be modified if it is to be used in the treatment of schizophrenia.

The general management of the schizophrenic presents many interesting problems. The majority of well-established cases must be treated in mental hospitals or sanatoria but often a farm or ranch is helpful and in mild instances if there is good cooperation, patients may be treated in their homes. Whether the patient be in a hospital or at home, adequate nursing, occupational therapy and proper social service are important. The nurse is the representative of the psychiatrist and if well trained she will know how to attempt to check the inroads of phantasy and how to set forth in theory and practice the claims and advantages of reality. The social service worker if not too fanciful is valuable in the "follow up" of adjusted patients, and when patients are treated at home she should combat the danger of family disorganization. Occupational therapy is an extremely valuable and a necessary treatment adjunct. It is constantly symbolic of reality rather attractively garbed and it produces concrete fruits of effort rather than phantasy.

The good nurse will know how necessary it is to see that the patient has sufficient nourishment, that he is tube fed when necessary, that he is kept clean, bathed frequently, changed when he wets or soils himself, that dangerous and sharp objects with which the patient might mutilate himself or others are not available, that the patient has enough exercise, sunshine and fresh air, that the chronic patient is taught useful habits and some routine at least in the care of bodily functions, and the nurse, too, will minimize and control the physical dilapidation of appearance which is such an early result of the shutting out of reality. The prolonged bath and wet packs sometimes quiet the excited states. Apathy often must be the target of special measures: walks, calisthenics, physical culture apparatus, athletic games, indoor games, cards, other diversions, suitable motion pictures and the theatre, music, dancing, garden work, arts and crafts, especially weaving and basketry are all helpful. Sometimes in stupor visiting by relatives is beneficial.

## THE DRASTIC THERAPIES

The drastic therapies which are being continuously improved contribute a long needed weapon to the armamentarium of psychiatric therapy.

The chief drastic therapies are insulin shock, convulsive therapy, metrazol or machine induced, and the surgical operation of pre frontal leucotomy.

The use of insulin shock therapy is largely restricted to schizophrenia. The twenty-one to thirty five age group and the paranoid and catatonic types are the more favorable. The shorter the duration of the psychosis, the better the outlook. The prognostic indices are too loosely drawn and much treatment is given uselessly. Follow up studies made of schizophrenics ten years after insulin treatment indicate the real value of the treatment. Of 400 such patients treated in Swiss hospitals before 1937 59 per cent showed complete or social remission. Of a thousand cases treated in New York State hospitals 11.1 per cent re

covered, 26 5 per cent greatly improved and 26 per cent somewhat improved The corresponding figures for a control group of 1 000 untreated cases were 3 5 per cent, 11 2 per cent and 7 4 per cent

Contraindications to insulin shock therapy are cardiac arrhythmia due to organic disease of the conduction system, coronary disease severe myocarditis or valvular disease tuberculosis, organic impairment of the liver renal or pancreatic functions severe endocrine dysfunctions

Convulsive therapy induced by the electric machine has largely replaced metrazol, is extremely satisfactory and with intelligent selection of patients and skillful administration the danger is very slight It may be modified by curare It is very useful in manic-depressive, notably in involutional melancholia and in a considerable segment of schizophrenia

The contraindications are marked arteriosclerosis and hypertension pregnancy, marked bony changes either hyperplastic or degenerative seropositive syphilis tuberculosis, cachexia cardiovascular disease

The highest recovery rate in any large and varied group of cases initially diagnosed as schizophrenia will be achieved when insulin and convulsive therapy are skillfully combined in differing proportions in each case based on the actual symptomatology shown (Sargent and Slater )

The operation of pre frontal leucotomy has a limited but important application It has been used in involutional melancholia schizophrenia and a number of very severe anxiety neuroses and obsessive compulsive neuroses It is our feeling that criteria under which the operation was done in schizophrenia should be applied whenever the operation is contemplated

The main criteria are as follows (1) that the condition has been determined to be chronic and hopeless through clinical study (2) that all other methods of treatment have failed (3) that the operation does not entail undue risk *

It is extremely important that the use of the drastic therapies should not discount or minimize psychotherapeutic attention to the patient

## THE NEUROSES

In the consideration of the neuroses such an enormous clinical field is opened that it is extremely difficult to treat it briefly One may only acknowledge without discussion the enormous debt which modern psychiatry owes to Binet Janet Babinski Freud and the psychoanalytic school Adolf Meyer and many others

The neuroses may scarcely be considered even in brief presentation without some reference to psychopathology since the frequency of failure to diagnose and treat and above all to understand strikingly illustrate an outstanding and urgent need of a firm belief in the existence of a valid pathology which is not expressed in demonstrable structural damage There is a point beyond which physical diagnostic efforts and therapy may become harmful and even pernicious This is certainly so if they exclude a consideration of emotional factors if they are intensively and solely directed at the correction of minor and conjectural physical defects such as slight deviations of the nasal septum on the assumption that a minor operation will cure a psychoneurosis or finally if they are mistakenly focused on the physical expression of underlying emotional states

Psychotherapy in its modern sense presupposes the acceptance of at least a minimum of psychopathologic doctrine It is extremely difficult and hazardous to state what such a minimum implies Many of the signs and symptoms familiar to the organic neurologist for instance sensations have representations in the consciousness of his patient In a sense therefore, he studies minds the content of which the subjects are clearly aware and he studies and questions his patients chiefly from the standpoint of elucidating the findings obtained in his examination The psychiatrist

* Other psychosurgical procedures are trans orbital lobotomy topectomy thalamotomy and selective cortical undercutting They all are based on the assumption that those frontal lobe fibers which are connected with the ventral nucleus of the thalamus have to do with emotional overtones and that destroying these fibers will prevent anxiety of pathologic intensity Psychosurgery is still in the investigative stage and awaits final clinical evaluation —Editor

studies another mind, the content of which the patient does not clearly perceive, a not conscious mind, the investigation of which is profitable to the psychiatrist, since it contains a record of what has happened to the person during his lifetime (*See* Chapter 20)

*Classification* —The classification of the psychoneuroses is far from complete which is satisfactory enough for the present since it represents a state of flux awaiting additional knowledge Freud includes 'irritable weakness' or neurasthenia, anxiety states embracing anxiety neuroses' and 'anxiety hysteria', hysteria and obsessive and compulsive psychoneuroses Ross puts forward the suggestion that all neuroses represent faulty responses to difficulties In effect they constitute attempts to escape (1) By overreaction resulting in neurasthenia including the anxiety neuroses and anxiety hysterias of other writers (2) by underreaction or failure to react at all, resulting chiefly in conversion hysteria (3) pretending that the difficulty does not exist resulting in compulsion neuroses We shall employ a very simple classification hysteria, neurasthenia compulsion neuroses and anxiety neuroses

Naturally a real understanding of the neuroses must be derived from a study of underlying conflicts and mechanisms but a brief symptomatic list may be helpful

## HYSTERIA

*Somatic Symptoms – Sensory* Hyperesthesias hypoesthesias and anesthesias which are all non-explainable on any organic basis, narrowing of the visual fields photophobia, blindness hyperacousis deafness anosmia loss of taste headache *Motor* Paralyses of all varieties flaccid or spastic and sometimes with contracture Conclusive neurologic evidence of organic disease is wanting All types of abnormal movements—clonic choreiform, tremors—occur Pathologic attitudes and gaits may be displayed Every kind of vasomotor symptom may appear and muscular atrophy is not extremely uncommon The e manifestations are sometimes so striking that the French school of neurologists have attempted to differentiate such cases from true hysteria and have given them a separate grouping halfway between organic and functional disease, under the name of 'reflex paralyses' In addition to the symptoms which mimic usually in crude fashion every syndrome resulting from organic nerve irritation or defect, there may be exhibited many unusual phenomena such as rhythmical movements of various parts of the body head noddings, rotations and also bizarre attitudinizing The classical, full fledged convulsion is not usual though abortive and partial convulsive seizures are seen fairly often Perversion or loss of special function aphonia or mutism difficulty or inability of swallowing, globus vomiting amenorrhea, anuria, constipation or diarrhea may be a part of the symptom-complex

*Mental Symptoms* —*Amnesia* which is apparently a successful subconscious effort to keep something out of the field of consciousness It may extend for a considerable period before and beyond a particular incident or experience *Fugue* A span of time for which the patient is amnesic though during the fugue his actions are such that it seems to the observer that he must be conscious of his surroundings *Double personality* The fugue and the amnesic period probably have a content which is not acceptable to ordinary personal consciousness and therefore, there is acquired a kind of new consciousness constituting a second personality *Hallucination* It has been explained on the basis of partial failure in attempting to submerge a disagreeable complex the remnant remaining as an hallucination There may also be somnambulism hysterical fits deliriums, trances, stupor or dream states

## NEURASTHENIA

*General Symptoms* —*Fatigue* Often present on slight exertion and may be curiously selective in that it is chiefly manifested when the patient's interest is at low ebb Loss of weight Usually dependent on an appetite failure

*Local Symptoms* —*Alimentary* Capricious appetite anorexia, indigestion distention eructation nausea vomiting constipa

tion or diarrhea mucous colitis *Circulatory* Varying degrees of cardiac discomfort tachycardia palpitation pseudo-anginal sensations heart irregularity *Vasomotor* Pallor blushing sweating coldness, heat and numerous other phenomena *Genitourinary* Impotence nocturnal emissions genitourinary paresthesias dysmenorrhea dyspareunia frequency of micturition increased urinary output "loose kidney", *Respiratory system* Frequent "colds", shortness of breath sometimes hastened respiratory rate with shallow breathing *Nervous system* Peculiar sensations in head and in fact in every portion of the body feelings of swelling of scalp band around head bursting and stuffiness of head headache especially in occipital region peculiar uncomfortable or painful sensations in the abdomen rectum or breasts An almost universal complaint is backache Giddiness and dizziness are common and insomnia is rarely absent There may be photophobia musce volitantes and eye muscle fatigue ear noises intolerance of ordinary sounds *Mental symptoms* Inability to concentrate uncertain memory fear of insanity awkwardness and self consciousness in the presence of others feeling of inferiority irritability depression phobias anxieties

## COMPULSION NEUROSES

The clinical boundaries of the obsessive and compulsion neuroses are not clearly defined There is a group of symptoms including obsessions impulsions feelings of insufficiency nervous tension and anxiety Sometimes the obsessive thinking is ruminative consisting of preoccupations which "obsess" the mind but do not result in compulsive behavior However the step from obsessive thinking to obsessive behavior is natural and easy Obsessive acts symbolic of underlying trends are legion There are numerous ritualistic actions such as touching certain articles avoiding certain places and things food rituals or clothing rituals such as arranging clothes in exactly the same pattern after disrobing at night

## ANXIETY NEUROSIS

Anxiety neurosis or anxiety state a clinical type in which morbid anxiety or fear is the most prominent feature A general nervous irritability (or excitability) is regularly associated with the anxious expectation or dread In addition there are numerous physical symptoms which may be regarded as the bodily accompaniments of fear particularly cardiac and vasomotor disturbances the heart's action is increased often there is irregularity and palpitation there may be sweating nausea vomiting diarrhea suffocative feelings dizziness trembling shaking difficulty of locomotion Fluctuations occur in the intensity of the symptoms acute exacerbations constituting the "anxiety attack"

### Psychogenetic Considerations

The vast territory embraced by the neuroses is still too virginal to permit one to disregard a single possible determining factor Organic aspects a better evaluation of nerve fatigue endocrine influence all need additional rigid investigation In each patient there is demanded a carefully scrutinizing physical survey and treatment of the discovered pathology whether or not it be considered etiologic It is nevertheless true that at present at least psychologic investigation and therapy are more fruitful

Psychologically hysteria is resultant upon repression and subsequent conversion There is psychic trauma Painful ideas which for the particular individual are unacceptable to the conscious mind are not given an emotional outlet but are relegated or forced or *repressed* into the subconscious mind and become buried complexes The said painful ideas according to the Freudian school have invariably a sexual content Such repression often takes place during childhood Later these buried complexes are converted or rather the affect (emotion) with which they were associated is converted into a symbol which is objectively evident as an hysterical symptom

In a non Freudian sense an illustration may serve to clarify After a sharp action during World War I, a soldier was left

lying upon the field of battle. He feared to move because of the danger of an enemy sniper's bullet and for many hours he was compelled to remain rigidly quiet, surrounded by the dead and listening to the horrible cries and groans of dying. Later, he was led into an ambulance dressing-station totally deaf, although his hearing apparatus was physiologically intact. He was simply hysterically deaf and, furthermore he was amnesic. He remembered the action and could recall being brought to the ambulance dressing station but for the hours spent on the battlefield his mind was a complete blank.

What is the psychologic explanation? One may think of the horrors of war fatigue and exposure as directly causative of this hysteria. They were not. Even the emotion racking experience on the battlefield at most determined the time of the actual appearance of the hysteria. The dynamic mechanism, as always, was the conflict. In this instance, the conflict was between the instinct of self preservation and contrasting and opposed self and soldierly ideals. Self preservation triumphed, the conflict came to resolution and was converted into two disabling and protective symptoms—deafness and amnesia.

Hysteria is a large subject and only a few significant conceptions may be given. (1) Suggestion is an important factor. Babinski believed it alone served to explain hysteria. He felt that the symptoms were purely the result of suggestion and proposed for hysteria the designation 'pithiatism.' (2) The symptoms and signs of hysteria unlike those of neurasthenia, tend to be total such as deprivations of the special senses paralyses and anesthesias. (3) The hysteric views his symptoms objectively, is less conscious of his personal problems or conflicts and is less emotionally tense than for instance, the patient who has neurasthenia or an anxiety state. (4) Almost always the functional nature of the symptoms may be detected since they tend to exaggerate rather than simulate organic nerve or somatic disease, and there are many discrepancies in the clinical picture unexplainable on an organic basis. (5) Hysteria is a simple, naive, childlike device and its mechanism is usually not too difficult to penetrate.

*Neurasthenia* and some of the anxiety states, too are faulty responses—attempts to escape from the difficulties and conflicts of life. Freud stressed, as causative in neurasthenia, excessive masturbation in adult life and incompleteness of sex satisfaction. He stated that anxiety neuroses are more common in women and attributed them to coitus interruptus or ejaculatio præcox, in men to abstinence, frustrated sexual excitement coitus interruptus or senile conditions. Nonsexual stresses may be operative. The mechanism consists in a "deviation of the somatic sexual excitement from the psychic and in the abnormal utilization of this excitement."

The physician must be on the alert to detect the neurasthenic complex which may be a precursor or accompaniment of serious organic disease as for instance, in paresis or brain tumor. Furthermore, he must constantly remember that neurasthenia does not exclude the presence of organic disease.

Neurasthenia develops much more gradually than hysteria. The fatigue that is such a prominent symptom is not as is so often taught the cause of neurasthenia. It is effect rather than cause and is the aftermath of a long battle of emotional cross purposes. In the neurasthenic the circle of normal interests and activities rapidly diminishes and contracts so that eventually the attention is rigidly concentrated upon somatic sensations and reflexes such as the heart beat peristaltic movements of the stomach and intestines, muscle and joint movements. In neurasthenia these sensations and reflexes impinge upon the consciousness and are extensively elaborated while in normal health the individual is scarcely aware of their existence. It is true that in themselves they are unpleasant uncomfortable and even painful yet the center of psychologic attention has been shifted and the mind has escaped the even *more difficult and unpleasant facing* of problems and conflicts. Since the connection between the symptoms and the unsolved emotional problem is not open and direct in consciousness the psychopathologic mechanism employed saves the face of the

patient Not only is the ego spared the humiliation of self-criticism but social censure is avoided

Some of the symptoms encountered in the evolution of neurasthenia and the anxiety states have their analogies in the condition of a frightened animal let us say a cat frightened by a fierce dog The cat is in the grip of fear Physiologically the emotion acts by putting its body in the most efficient state for fight or flight The cat crouches, its skeletal muscles are tense, its hairs stand on end, the pupils are dilated there is a hissing noise the heart works rapidly the blood flows quickly and its pressure is increased breathing is quickened movements of the stomach and intestines are reduced to a minimum, and there are numerous and important ductless gland reactions

The human being is less often subjected to such acute and sthenic emotional crises but relatively the same effect is produced by less severe and more protracted emotional states resultant upon some serious life problem There may be apprehension anxiety worry shame, resentment and they as in the instance of the cat, are likewise expressed in the finely adjusted physical organism In the beginning the symptoms probably represent a fighting attempt to overcome the difficulty Eventually struggling and aggressiveness cease The individual is defeated He retires from the world of everyday normal distribution of interests and energies and engages in a close consideration of and an endless introspection into various residual sensations The typical neurasthenic patient with his great variety of subjective somatic complaints has now been produced

To illustrate let us picture a quarrel between husband and wife The subject of contention is the third member of the household the mother of the wife a querulous complaining and rather disturbing invalid to whom however the daughter is devoted For years husband and wife have quarreled about her presence in the home The husband wants her to leave The wife coaxes threatens gets into a violent temper weeps The husband goes to business The wife for the hundredth time feels herself driven into a corner Suddenly she is sick There is the sensation of an aching band about her head she is weak and tired her muscles are sore her heart seems to be racing along she is nauseated and faint She analyzes these sensations minutely What dreadful illness is threatening her? Heart disease? Actually she is organically sound The diagnosis is neurasthenia

In the background of this case there were many years of worry The conflict has been protracted and for this woman it has been very serious On the one side of the balance devotion to her mother and the dread of having her go to an institution on the other anxiety about her husband s love and the fear of losing him The conflict produced friction and fatigue The destructive emotional state began to be expressed by various physical sensations At first they were only occasional and insignificant manifestations Finally they became constant and alarming They demand consideration and treatment and a pathologic escape from an apparently unsolvable problem has been made unconsciously available

*Psychasthenia* which includes a large segment of the territory now occupied by the compulsion neuroses was regarded by Janet as a lowering of the psychologic tension , Meyer defines it as a lowering of general interest and tendency to rumination over what is accessible to the patient in his memory but is not squarely met and where the normal reaction is replaced by rumination substitution acts and panics Ross puts forward the suggestion that psychasthenia is a faulty response involving an effort to pretend that the conflict or difficulty does not exist

In any event psychasthenia apparently utilizes the psychologic mechanisms of displacement substitution and symbolism

As an example we may cite Ross interesting case of psychasthenia in a man who was obessed by a superstitious fear of the number 13 He remained in bed on the thirteenth day of the month hopped over each thirteenth step counted the syllables in conversations and felt a shock at the thirteenth or its multiples would not walk in Oxford Circus because of a sign Peter Robinson containing thirteen letters and

had numerous other disabling symptoms all associated with the number 13

*Modified analysis elicited that during* his boyhood there has been an ignorant superstitious serving maid in the home who had attempted sex relations with the boy Subsequently he had been sent to a boarding school and had lived for some years in a rigid religious atmosphere The disgusting experience of childhood had passed beyond the ken of conscious awareness The neurosis with the obsessive reaction to the number 13 had appeared in middle adult life

One may assume originally a conscious union between the idea of sex experience and the unhappy emotions (disgust fear shame remorse) called forth by the remembrance Soon the idea becomes too troublesome unpleasant and painful to be retained in consciousness where it must be constantly viewed By *means of the psychologic* mechanism of displacement the union is severed and the repugnant idea is dropped into the unconscious This leaves free and unattached the emotion from which the idea has been detached The emotion is then attached to a concept in itself innocuous in this case 13 Thus 13 becomes a substitute for and a symbol of the for gotten ' sex episode The second union is not altogether successful There is the tendency for the original idea to reappear and whenever there is any danger that it may break through into consciousness then there are manifested the frantic obsessive devices or symptoms related to the number 13

Frequently psychasthenia may be re*traced* to childhood experiences Not only sex experiences *can* be *dynamic* but anything that induced a vivid and strong emotional reaction that was never cleared up or explained and was finally repressed

The almost *uniform* occurrence of characteristic reactions in the history and clinical findings together with the favorable results of active treatment instituted at relatively late periods in the *course* of psychasthenia leads us to the conclusion that many psychoneurotic conditions might be prevented by early recognition and proper management The possible mental and emotional effects of diseases, accidents, operations and financial, sex and marital disturbances should be considered in the case of every patient consulting a physician

TREATMENT

General therapeutic indications are given since not only the particular neurosis, but the individuality of the patient and his *setting in life will often determine* modifications

Details of treatment which vary from patient to patient include hospital or rest house care rest in bed scientific nursing dietary control, massage hydrotherapy electrotherapy, occupational therapy supervision of the patient s activities, including visitors, correspondence reading graduated exercise tonic and in extreme conditions hypnotic medication There must be correction of any *actual* organic pathology

The principles of treatment for the neu*roses as developed at Stockbridge by Riggs* are as follows The patient is given an opportunity to tell his story in detail Next there is a thorough physical and mental examination followed by a frank discussion with the patient *concerning his* difficulties and the reasons for his maladaptation The patient is then informed of the plan of treatment and is given a daily schedule to meet his individual needs It consists of exercise, diversion and *rest* The keynote of the treatment is re-education It stresses the importance of dominating the emotions and of utilizing the intelligence to guide conduct Efficiency is emphasized The patient is impressed with the necessity of making clear cut decisions at first in trivial later in graver matters The *proper* use of the mind is described The harmful effects of worry unnecessary hurry inattention and self pity are elaborated They are manifestations of inefficiency The patient is instructed concerning rest which is not synonymous with sleep and is chiefly the temporary and volitional abandonment of responsibility

As a general guide toward rehabilitation the following steps are logical and helpful

1 *Establishment of Rapport Between the Physician and Patient* —This rapport to be effective must be based on a certain *amount* of respect and confidence on the part of the patient It is best furthered by a careful

investigatory program instituted by the physician at the first interview

2 *Aeration or Ventilation* — Aeration or ventilation of the conflict material presented by the patient may be carried out by means of Freudian catharsis by means of direct interviews by means of discovering and probing for such material from outside sources by hypnosis or by any other method The important thing is that the patient is given an opportunity to discharge and bring out in the open all of those life experiences which have been causing him serious concern either consciously or unconsciously

3 *Desensitization* —Desensitization is the procedure wherein the patient is required to face frankly the traumatic and unpleasant experiences of his past It is brought about in the first place by causing the patient to discuss at frequently repeated interviews the conflict material as elicited above These interviews are repeated until the patient can review these experiences without excessive emotional concern

4 *Re-education* —Re-education is carried out in connection with all of the above procedures It is essentially the development of clear insight on the part of the patient into the mechanism of his illness the establishment of new habits of response (as in desensitization) and the formulation by him of an adequate industrial social recreational and activity program to ensure future stabilization

5 In addition to the above it is often advisable to desensitize the patient s family to his illness and re-educate them into new habits of response toward the patient

6 All contributing physical factors are corrected as far as possible Measures for their correction are instituted at the earliest possible interview and are utilized as psychotherapeutic aids

## MILITARY NEUROPSYCHIATRIC DISABILITIES[1]

Neuropsychiatric disabilities because of their extremely high incidence are vital medico-military problems Not only are they extremely wasteful economically but much more than wounds they are disruptive of troop morale

Neuropsychiatric disabilities rarely appear with obvious diagnoses and there is a wide variety of symptoms and signs However the outstanding clinical segment is apt to be physical emotional or military misbehavior

A Physical ranging from convulsions coma lesser degrees of disturbances of consciousness paralyses deafness blindness severe headache, *etc*, to tics, limited anesthesias *etc*

B Emotional including depression often suicidal elation resentment irritability fear suspicion excitement, anger rage *etc* Admixtures are to be expected

C Military misbehavior embracing suspected fifth-column activities inciting to insubordination striking an officer drunkenness, neglect of duty grousing quarrelsomeness petty stealing *etc*

Unless the medical officer has some idea of the underlying nature of the emergency his treatment efforts are apt to be ineffectual or even harmful His examination should be extensive enough to answer the following questions Is it organic or functional? If organic is the seat of the disease outside the nervous system (uremic convulsions sinus headache *etc*)? If functional is it psychosis or psychoneurosis? If psychoneurosis is it the usual war neurosis conversion hysteria or a less frequent neurosis—neurasthenia anxiety obsessive-compulsive?[1] Can the disabling symptoms be speedily removed? Is it malingering?

The medical officer must not expect elaborate histories and in the field at best there will be available only a part of the information Reliable sources of information are the sick soldier s officers top sergeant and buddies

The medical officer s most reliable diagnostic instrument is careful observation However a brief neurologic examination (temperature pulse pupillary responses particularly to light tendon reflexes notably KJ abdominal and cremasteric reflexes

The senior author refers by permission to his contribution to TM8-120 Technical Manual Guides to Therapy for Medical Officers War Department March 20 1942

[1] In World War II anxiety states were more common than conversion hysteria

Romberg's sign, posture, gait *etc*) may furnish valuable diagnostic and treatment leads of neurologic and psychiatric conditions, for instance, multiple sclerosis and paresis The psychoses of senility are excluded by military age limits However, there may be profound dementia due to alcoholism, epilepsy, brain tumors, presenile pathology, *etc*

Determined in practice by military exigencies, the major portion of the mental examination is dependent upon observation By observing carefully much may be noted General appearance state of body, clothing, facial expression attitude motor activity and whether it is purposeful or aimless, related to the environment or not, catalepsy, *stupor, mannerisms* negativism, suggestibility echopraxia, *etc*

If accessible, the soldier should be discriminatingly questioned in order to confirm impressions of observational data or to *determine the presence of decided mood* alterations, overactivity or underactivity of thought and speech, illusions hallucinations, obsessions ideas of reference, delusions, orientation memory including amnesia intelligence *etc*

An estimate of the emotional state and of consciousness is a necessary condition of diagnosis and treatment In manic depressive the emotional display is likely to be fairly clear-cut depressed often with self-blame and suicidal trends or exhilarated with quick shifts to other emotional reactions *in schizophrenia the emotional* expressions tend to be inadequate to the verbally expressed thinking or even at odds with it

Once conversion hysteria is well developed there is less emotional disturbance than would be anticipated in view of the dramatic character of the symptoms in the other neuroses there is *overconcern tension* and anxiety fear panic and so on

In a general way and in the absence of epilepsy paresis deep depression or grave neurologic or toxic pathology, disturbances of consciousness are prognostically good omens In the recoverab war neuroses particularly those occurring in combat, there is often an initial *befogged state* perhaps immediately determined by concussion fatigue, or food deprivation Even more favorable are acute psychoses with delirium dependent upon physical exhaustion They respond readily to simple treat *ment such as hot food increase of fluid in* take, rest, explanation

Malingering is a deliberately planned attempt to evade military duty or secure a discharge by feigning illness While not easy to detect, yet usually the simulation is overdone or incomplete with the absence of fundamental signs and symptoms Various technics like warming a clinical thermometer or taking purgative medicines or self inflicted wounds, may be employed Treatment should never omit giving the malingerer a "chance" Not infrequently detection, confession and frank *explanatory* discussion will convert him into a good soldier

Often military misbehavior is incipient evidence of psychosis, psychoneurosis, or *even organic neurologic disease Successful* treatment depends upon uncovering the underlying condition and dealing with it It is important to determine whether the behavior is consistently below army standards (indicating mental defect constitutional psychopathic inferiority) whether there was a rather abrupt change in the behavior pattern (indicating manic-depressive *schizo*phrenia paresis) whether there was a gradual alteration (indicating alcoholism anxiety neurosis) Was the conduct marked by overaction as in the boisterousness *aggressiveness and violence* of mania paresis or schizophrenic excitement or as more often in schizophrenia by underreaction as in the passive withdrawal *from* companionship and activities? The psychologic setting in which the misbehavior occurred may at once suggest corrective treatment For instance is the soldier *homesick? Is he worried* about bad news from his family? Perhaps he has had a gossipy letter hinting that his wife or his girl is interested in another man

The common war neurosis in World War I was conversion hysteria in World War II anxiety states were more usual In treatment particularly the medical officer *should* have a *working theory* of development There is an underlying unconscious conflict

The demands of the instinct of self preservation strongly activated by moving emotions fear horror and revulsion, versus ideals of soldierly duty patriotism honor training and discipline reactions Under conscious worry stress fatigue, or physical shock the conflict may be converted into protective symptoms, the clinical war neurosis

A few facts are valuable treatment guides (1) War conversion hysteria is more likely to occur in the intellectually average soldier neurasthenic anxiety and obsessive compulsive reactions in the superior soldier and officer (2) The symptoms of hysteria appear much more abruptly than in the other neuroses (3) Conversion symptoms—especially in combat—are apt to be total symptoms blindness paralyses hemi anesthesias in the other neuroses they are more often partial—blurring of vision weakness paresthesias (4) Often conversion symptoms may be removed by simple psychotherapy—such as suggestion (5) In war hysteria the earlier the treatment is instituted the better the prognosis[1]

(1) Early treatment was highly important, since often it was possible to remove symptoms by simple suggestion (2) The most satisfactory results were obtained in soldiers showing initial clouding of consciousness (3) The critical psychotherapeutic treatment time is when consciousness begins to clear (4) As soon as favorable secondary emotional trends begin to emerge they should be shaped and strengthened by positive and negative suggestion

Making due allowance for the occurrence of the disability in encampments or in combat and for the availability of psychiatric consultation and facilities treatment should utilize the following considerations

1 As soon as possible a brief examination and interview to determine the symptoms and to gauge roughly the soldier s personality

2 Establishment of rapport

3 An attempt to remove some of the symptoms by persuasion and suggestion

4 Desensitization and simple explanatory therapy

5 The production of positively and negatively conditioned psychic reflexes Positive concerning the advantages of returning to the front or in camp to the pleasant associations of the outfit Negative painting evacuation in gloomy colors (loss of the chance to participate in the honors of the outfit separation from buddies *etc*)

In a group of soldiers who have made fairly good symptomatic recoveries but who persistently retained a few symptoms the question of volitionally withheld co operation must be considered Without using undue severity and without trace of malice such men soon found that an invisible barrier had been erected between them and the other patients They were denied certain privileges and were assigned a reasonable amount of work such as policing grounds and digging latrines No one was permitted to impugn their motives directly yet they were confronted by a questioning expectant attitude Always the opportunity was afforded and indirectly encouraged, of talking things over always there was the invitation and temptation to change their status to a less dubious and happier one

Hypnotic medication probably paraldehyde and the barbiturates for severe insomnia, tincture of belladonna for tension benzedrine sulphate for depressions particularly with slow and difficult thinking and hypotension sodium amytal 0 3 to 0 6 gram intravenously when needed to secure relaxation or even mild hypnoidal states in order to remove inhibition so that traumatizing experiences are brought to the surface and ventilated and that the soldier is desensitized and may begin to build insight Narcosynthesis with the use of sodium pentothal may be used Occasionally hypnotism is helpful In the subsequent treatment of the war neuroses group psychotherapy is of considerable service

[1] These are highly important considerations notably during combat when time limits for restoration to duty (often only a few days) must be rigidly observed What is said of treatment in the combat zone applies with equal force to soldiers in encampments or in quiet sectors In the zone of active combat the neurosis will be much more severe at the onset the consciousness may often be clouded there will be fewer and poorer treatment facilities yet the results will be better than in encampments sometimes reaching more than 70 per cent restorations

Romberg's *sign, posture, gait, etc*) may furnish valuable diagnostic and treatment leads of neurologic and psychiatric conditions, for instance, multiple sclerosis and paresis The psychoses of senility are excluded by military age limits However there may be profound dementia due to alcoholism, epilepsy, brain tumors, presenile pathology, *etc*

Determined in practice by military exigencies, the major portion of the mental examination is dependent upon observation By observing carefully much may be noted General appearance, state of body clothing, facial expression, attitude motor activity and whether it is purposeful or aimless, related to the environment or not catalepsy, stupor, mannerisms negativism suggestibility echopraxia *etc*

*If accessible the soldier should be* discriminatingly questioned in order to confirm impressions of observational data or to determine the presence of decided mood alterations overactivity or underactivity of thought and speech, illusions hallucinations, obsessions ideas of reference delusions, orientation memory including amnesia intelligence *etc*

An estimate of the emotional state and of consciousness is a necessary condition of diagnosis and treatment In manic depressive the emotional display is likely to be fairly clear cut, depressed often with self blame and suicidal trends or exhilarated with quick shifts to other emotional reactions in schizophrenia the emotional expressions tend to be inadequate to the verbally expressed thinking or even at odds with it

Once conversion hysteria is well developed there is less emotional disturbance than would be anticipated in view of the dramatic character of the symptoms in the other neuroses there is overconcern tension and anxiety, fear panic and so on

In a general way, and in the absence of epilepsy paresis deep depression or grave neurologic or toxic pathology, disturbances of consciousness are prognostically good omens In the recoverable war neuroses particularly those occurring in combat, there is often an initial befogged state, perhaps immediately determined by concussion fatigue, or food deprivation Even more favorable are acute psychoses with delirium dependent upon physical exhaustion They respond readily to simple treatment such as hot food, increase of fluid intake, rest explanation

Malingering is a deliberately planned attempt to evade military duty or secure a discharge by feigning illness While not easy to detect yet usually the simulation is overdone or incomplete with the absence of fundamental signs and symptoms Various technics like warming a clinical thermometer or taking purgative medicines or self-inflicted wounds may be employed Treatment should never omit giving the malingerer a "chance" Not infrequently detection confession and frank explanatory discussion will convert him into a good soldier

Often military misbehavior is incipient evidence of psychosis psychoneurosis, or even organic neurologic disease Successful treatment depends upon uncovering the underlying condition and dealing with it It is important to determine whether the behavior is consistently below army standards (indicating mental defect, constitutional psychopathic inferiority), whether there was a rather abrupt change in the behavior pattern (indicating manic depressive schizophrenia paresis) whether there was a gradual alteration (indicating alcoholism, anxiety neurosis) Was the conduct marked by overaction, as in the boisterousness aggressiveness and violence of mania paresis or schizophrenic excitement or, as more often in schizophrenia by underreaction as in the passive withdrawal from companionship and activities? The psychologic setting in which the misbehavior occurred may at once suggest corrective treatment For instance, is the soldier homesick? Is he worried about bad news from his family? # Chapter 32

# Organic Diseases of the Nervous System

By GEORGE WILSON M D  CHARLES RUPP M D
HARVEY BARTLE Jr M D and WILLIAM W WILSON M D

## INTRODUCTION

No branch of medicine requires so detailed a knowledge of the functioning of the entire body as does the study of nervous and mental diseases To be equipped properly to diagnose and treat nervous disorders one should have an adequate training in internal *medicine as well as a good knowledge of the* form and function of the nervous system The nervous system is a vital part of the total body economy not an isolated organ system Infections such as syphilis and tuberculosis vascular disease and tumors all affect the nervous system at times just as they affect other parts of the body and a full understanding of these factors requires some knowledge of their effect on the other parts of the body

The physician or student should train himself to make as accurate a diagnosis as possible by careful observation of the patient s signs and symptoms and their correct interpretation in light of his knowledge of the structure function and pathology of the nervous system In some cases determination of the exact diagnosis may be impossible without detailed laboratory and other special studies such as encephalography but recourse to such studies without prior careful observation and correct reasoning leads only to a machine made diagnosis much to be deprecated

The *history* in a nervous case is often of more importance than a good examination It should be taken carefully, in chronologic order and, as far as possible in the patient's own words Sometimes the patient will have to be directed in this story but an effort should be made not to ask leading questions This is more important when one is dealing with a functional rather than an organic case An idea of the patient s past life his heredity his mode of living his recreations and vices if any is important As the case unravels itself questions will suggest themselves to the examiner For example a complaint of pain should always be elaborated upon particularly its location its reference if any its character the presence of anything which aggravates it such as moving or coughing the time of day it occurs and if present at night whether it prevents sleep or awakens the individual Functions of the sphincters especially that of the bladder should be carefully inquired into Difficulties in the control of the urine which make their first appearance after the age of fifteen or twenty years will quite often have to do with involvement of the central nervous system If a local cause cannot be found for difficulty in the control of the bladder sphincter it is usually nervous in origin Direct questions should always be asked as to the presence of visual difficulties such as dimness of vision or diplopia Questions referable to the eighth nerve that is the presence or absence of tinnitus vertigo and deafness should be inquired about The history of the onset of an infection will often serve to make partially clear the type

than one seen in consultation in a hospital bed or at home In like manner the examination of patients on a ward service in hospitals will vary according to whether or not they are ambulatory The mental state of the patient can often be well evaluated during the interview His general emotional state the orderliness with which he gives his history, his memory and the presence or absence of such things as depression excitement and lethargy will be observed If he is delirious or comatose the history of the case will have to be given by someone else

After the mental status of the patient has been determined he should be weighed and his height taken He should then be completely undressed and the examination carried out in the following manner

SCHEME FOR NEUROLOGIC EXAMINATION

1 MENTAL STATUS Behavior disturbances of consciousness such as somnolence stupor or coma attention character and content of talk delusions illusions hallucinations emotional state orientation memory intelligence judgment insight Special tests such as the Binet-Simon

2 CRANIAL NERVES
 (a) *Olfactory* Sense of smell in each nostril
 (b) *Optic* Visual acuity—fundi examination Visual fields
 (c) (d) (e) (*Oculomotor trochlear abducens*) Equality of palpebral fissures movements of extraocular muscles nystagmus strabismus convergence
 Pupils—size shape equality regularity reaction to light direct and consensual reaction to accommodation
 (f) *Trigeminal* Sensory—sensation of the face corneal reflex Motor—action of the muscles of mastication
 (g) *Facial* Motor—voluntary and emotional movements of the facial musculature (peripheral and central types of facial palsy ) Sensory—taste over anterior two thirds of tongue
 (h) *Auditory* Acuity of hearing vertigo tinnitus Special tests such as Weber Bárány Rinné
 (i) (j) *Glossopharyngeal and Vagus* Sensory—taste over posterior third of tongue sensation of pharynx larynx gag reflex Motor—movements of palate swallowing phonation
 (k) *Spinal Accessory* Movements of sternocleido mastoid muscles and upper part of trapezius
 (l) *Hypoglossal* Movements of tongue

3 REFLEXES
 (a) *Superficial* Plantar cremasteric abdominal Tromner
 (b) *Deep* Patellar Achilles triceps biceps radial periosteal
 (c) *Visceral* Sphincter control sexual potency, priapism

4 MOTOR FUNCTIONS
 (a) Convulsions general or localized details about fits
 (b) Muscle power whether completely paralyzed or only weak Distribution of the involvement such as hemiplegia paraplegia and monoplegia Test strength of hands with dynamometer and other joints against resistance
 (c) Type of paralysis whether flaccid or spastic—muscle tone
 (d) Muscle atrophy or hypertrophy
 (e) Tremors or irregular movements such as fibrillary tremors athetosis chorea Parkinson s tremor, tics
 (f) Coordination tests finger to-nose test diadochokinesis heel to knee test
 (g) Station gait
 (h) Speech
 (i) Right or left handedness
 (j) Posture and attitude

5 TROPHIC FUNCTIONS
 (a) Muscular atrophy response of muscles to faradism and galvanism
 (b) State of skin eruptions ulcers glossy skin, herpetic eruptions bed sores arthropathies spontaneous or pathologic fractures

6 SENSORY FUNCTIONS
 (a) Subjective symptoms such as pain its type location radiation frequency conditions and postures relieving or aggravating it paresthesiae and dysesthesiae
 (b) Headache location type periodicity conditions aggravating it whether accompanied by nausea vomiting or vertigo
 (c) Tenderness hyperesthesia its location if present
 (d) Objective sensory tests for touch pain, hot and cold vibratory sense stereognosis sense of position deep pressure pain spot localization graphesthesia compass test All abnormal sensory results should be charted Objective sensory examination should be done when the patient and examiner are not tired or disturbed in a warm room preferably at the beginning of the examination and in the morning

7 VEGETATIVE NERVOUS SYSTEM
 (a) Cervical sympathetic size of the pupil enophthalmos exophthalmos narrowing of the palpebral fissure flushing or sweating of the face neck and upper extremities the reaction of the pupil to cocaine

of lesion from which the patient suffers Vascular accidents in the central nervous system usually produce sudden or apoplectiform onsets A tumor growing in the brain or the cord may take weeks or even years to produce the syndrome which the examiner sees, although it must not be overlooked *that occasionally the onset in a case of* spinal or brain tumor may apparently be sudden, the tumor may grow slowly and produce few or no symptoms until a hemorrhage suddenly occurs Because nerve fibers can function through a glioma, such a tumor may attain a large size before the symptoms are produced or before a hemorrhage suddenly occurs into it The progress of symptoms produced by an abscess is usually midway between a vascular accident and a tumor The relation, if any of a nervous condition to injury or an infection should be carefully inquired into Many patients with chronic encephalitis were but mildly ill with the acute attack which may have been entirely overlooked questions therefore, must be asked as to the occurrence of an illness characterized by double vision, *lethargy or perhaps insomnia* The sequence of events is an extremely important part of the history double vision occurring early in a history suggestive of brain tumor is of localizing importance, but if it occurs late *it may be simply a manifestation of a general* increase of pressure The character of a headache, if complained of should be closely scrutinized, and the index of suspicion of the examiner for such things as cerebral syphilis, brain tumor sinus disease and eye strain should be high If a spinal tumor is suspected the location of the original pain and the exact order of the development of symptoms is most necessary for a satisfactory diagnosis The examiner should be alive to the possibility that pain even though present in the abdomen or chest may be due to an involvement of a spinal root and that such a pain, because it is increased by coughing or sneezing, may simulate pleurisy *Root* pain is not as a rule, developed or aggravated by deep breathing

In obtaining the history of a patient suffering from convulsions it is important to inquire into aura, cry whether or *not he* injures himself in falling, bites the tongue, loses control of the urine and sleeps after an attack If there is a possibility that the *case may be hysterical the symptoms should* be put to the patient in a negative manner She should be asked "Of course, you never bite your tongue and never have a headache after a fit?" The same procedure should be *followed* when the abdomen or other parts are examined, not only by the student in neurology in search of knowledge, but also by the surgeon There can be no doubt but that many patients suffering from pain in the appendiceal region have it suggested to them by a surgeon who poking his finger into McBurney's point, asks in a suggestive tone, That hurts you doesn t it? The history of a paresthetic phenomenon is sometimes a great aid in arriving at a diagnosis Pernicious anemia and multiple neuritis are probably the commonest causes of numbness in the toes and fingers Questions should not be omitted pertaining to the general health of the patient Symptoms referable to the lungs heart and gastrointestinal tract should be particularly inquired into How the patient spends his *spare time if he has any* whether or not he has a hobby whether he plays golf and whether or not he takes too keen delight in the pleasure of the table may have a bearing on his condition and lead to a correct *evaluation of the symptoms* A good history is one of the most important things which leads to a correct diagnosis By the time a good history is obtained, certain leads will be indicated as to the location of the lesion and the type *of examination indicated* It is always wise however to have a definite examination routine which should not be neglected in the early years of practice For this reason some authorities believe that *only by taking a history and recording* the examination on a form will a complete and detailed result be obtained

When the *examination* is made it should be done in a routine systematic manner and *while there are many variations in* the method of starting an examination, much will depend upon the circumstances under which the patient is seen as to the exact order in which various tests should be done *It is obvious that a patient seen in an office* will be put through a little different routine

than one seen in consultation in a hospital bed or at home In like manner the examination of patients on a ward service in hospitals will vary according to whether or not they are ambulatory The mental state of the patient can often be well evaluated during the interview His general emotional state the orderliness with which he gives his history, his memory and the presence or absence of such things as depression excitement and lethargy will be observed If he is delirious or comatose the history of the case will have to be given by someone else

After the mental status of the patient has been determined he should be weighed and his height taken He should then be completely undressed and the examination carried out in the following manner

of lesion from which the patient suffers. Vascular accidents in the central nervous system usually produce sudden or apoplectiform onsets. A tumor growing in the brain or the cord may take weeks or even years to produce the syndrome which the examiner sees, although it *must not be overlooked* that occasionally the onset in a case of spinal or brain tumor may apparently be sudden, the tumor may grow slowly and produce few or no symptoms until a hemorrhage suddenly occurs. Because nerve fibers *can function through a glioma, such a* tumor may attain a large size before the symptoms are produced, or before a hemorrhage suddenly occurs into it. The progress of symptoms produced by an abscess is usually midway between a vascular accident and a tumor. The relation, if any, of a nervous condition to injury or an infection should be carefully inquired into. Many patients with chronic encephalitis were but mildly ill with the acute attack, which may have been entirely overlooked; questions, therefore, must be asked as to the occurrence of an illness characterized by double vision, lethargy or perhaps insomnia. The sequence of events is an extremely important part of the history, double vision occurring early in a history suggestive of brain tumor is of localizing importance, but if it occurs late it may be simply a manifestation of a general increase of pressure. The character of a headache, if complained of, should be closely scrutinized and the index of suspicion of the examiner for such things as cerebral syphilis, brain tumor, sinus disease and eye strain should be high. If a spinal tumor is suspected the location of the original pain and the exact order of the development of symptoms is most necessary for a satisfactory diagnosis. The examiner should be alive to the possibility that pain, *even though* present in the abdomen or chest, may be due to an involvement of a spinal root, and that such a pain, because it is increased by coughing or sneezing, may simulate pleurisy. Root pain is not, as a rule, developed or aggravated by deep breathing.

In obtaining the history of a patient suffering from convulsions it is important to inquire into aura, cry, whether or not he injures himself in falling, bites the tongue, loses control of the urine and *sleeps after an* attack. If there is a possibility that the case may be hysterical the symptoms should be put to the patient in a negative manner. She should be asked, 'Of course, you never bite your tongue and never have a headache *after a fit?' The same procedure should be* followed when the abdomen or other parts are examined, not only by the student in neurology in search of knowledge, but also by the surgeon. There can be no doubt but that many patients suffering from pain in the appendiceal region have it *suggested to* them by a surgeon who, poking his finger into McBurney's point, asks in a suggestive tone, 'That hurts you, doesn't it?' The history of a paresthetic phenomenon is sometimes a great aid in arriving at a diagnosis. Pernicious anemia and *multiple* neuritis are probably the commonest causes of numbness in the toes and fingers. Questions should not be omitted pertaining to the general health of the patient. Symptoms referable to the lungs, heart and gastrointestinal tract *should be particularly in*quired into. How the patient spends his spare time, if he has any, whether or not he has a hobby, whether he plays golf and whether or not he takes too keen delight in the pleasure of the table may have a bearing on his condition and *lead to a correct* evaluation of the symptoms. A good history is one of the most important things which leads to a correct diagnosis. By the time a good history is obtained, certain leads *will* be indicated as to the location of the lesion and the type of examination *indicated*. It is always wise, however, to have a definite examination routine which should not be neglected in the early years of practice. For this reason some authorities believe that only by taking a history and recording the *examination on a form* will a complete and detailed result be obtained.

When the *examination* is made it should be done in a routine, systematic manner, and while there are many variations in the method of starting an examination, much will depend upon the circumstances under which the patient is seen as to the exact order in which various tests should be done. It is obvious that a patient seen in an office will be put through a little different routine

the nerve within the ball of the eye is the site of inflammation it is spoken of as *optic neuritis* There is no sharp line of demarcation between optic neuritis and choked disk or papilledema as far as the opthalmoscopic appearance is concerned however in optic neuritis the visual acuity is markedly impaired early and the fields show a central scotoma In papilledema visual acuity is usually only slightly diminished until late and the blind spot is enlarged The changes in the eye-ground which occur and which are of great importance from a neurologic point of view are atrophy optic neuritis and choked disk Optic atrophy is either primary or secondary Primary atrophy is due to direct involvement of the nerve It is usually bilateral and is a particularly common symptom in neurosyphilis especially tabes exogenous poisoning such as arsenic lead quinine tobacco carbon monoxide and above all alcohol These poisons act by producing a retrobulbar neuritis which leads in time to optic atrophy Infectious diseases may produce retrobulbar neuritis and the optic nerves may also be involved in multiple neuritis Retrobulbar neuritis is frequently the earliest manifestation of multiple sclerosis A large hemorrhage from any part of the body may occasionally produce optic atrophy

Inflammatory reactions or neoplastic conditions in or about the chiasm and suprasellar tumors often give rise to primary atrophy In fact the presence of optic neuritis or choked disk points decidedly away from lesions of the pituitary In amaurotic family idiocy (Tay-Sachs disease) optic atrophy occurs often with a characteristic cherry red spot in the macula area

A combination of optic atrophy on the side of the lesion and choked disk on the opposite side has been described in frontal lobe tumor

Retrobulbar neuritis is often followed by optic atrophy usually more marked on the temporal side of the disk Some time elapses before the pallor is seen The most characteristic visual field defect is bilateral central scotoma for red blue and green The visual affection is due to an interstitial neuritis of the papillomacular bundle Sphenoid and ethmoid diseases may produce either retrobulbar neuritis or optic neuritis Optic neuritis may occur also from any toxic or infectious cause such for example as kidney disease and diabetes The disk may be raised somewhat and the differential diagnosis between neuritis and papilledema may be a difficult one

Choked disk or papilledema is a not uncommon finding in cases with increased intracranial pressure The choking of the nerve occurs at the optic foramen Choking is characterized by overfilling of the veins contractions of the arteries swelling and blurring of the disk and by haziness of the margins A high degree of choking of the disks is compatible with good or normal vision but the visual acuity may be diminished In most cases of choked disks hemorrhages and exudates may be seen at the nerve head Choked disk is usually bilateral but may be more marked on one side At least 90 per cent of the patients suffering from choked disk have brain tumors Syphilis meningitis ependymitis sinus disease anemia infections and toxemias account for the remaining 10 per cent Enlargement of the blind spot and contraction of visual fields are common signs accompanying choked disk Each patient exhibiting choked disk should be considered as harboring a brain tumor until proved otherwise

The exact determination of the state of the visual fields is of the greatest importance in the localizing of cerebral lesions It is often advisable to repeat the examination particularly if the patient is dull or the examiner hurried A change may occur as a natural result of the disease which may clinch the localization

## Third Fourth and Sixth Nerves

The third nerve supplies all the muscles of the eyeball with the exception of the external rectus superior oblique and the dilator of the pupil The sphincter of the iris and ciliary muscles are supplied by the third nerve It also in part supplies the levator palpebræ The fourth (trochlear nerve) supplies the superior oblique whose function is to move the eyeball downward and outward The sixth nerve supplies the

## THE CRANIAL NERVES

### FIRST NERVE

Loss of smell (anosmia) may be due to disease in any part of the olfactory pathway

The sense of smell is tested by using volatile odoriferous substances such as oil of cloves coffee, camphor and peppermint Ammonia and acetic acid should not be used as they irritate the trigeminal nerve Each nostril is tested separately, the other being held closed

Since anosmia is commonly due to local nasal disorders such as polypi and acute rhinitis, little neurologic emphasis can be placed on a loss of smell unless local nasal pathology is definitely excluded In the absence of local disease unilateral anosmia may be of significance It occurs in fractures through the base of the skull in basal leutic meningitis in tumors which compress the olfactory pathways and in hysteria *Olfactory hallucinations usually of a disagreeable nature occur in the so called uncinate fits as well as in mental disease*

### SECOND NERVE

The examination of the optic nerve is one of the most important parts of the neurologic examination Vision may be tested by asking the patient to count fingers or by Snellen's test type Changes in the visual fields can be roughly determined by the examiner bringing into the field of vision from all directions his own hand the fingers of which are either moving or still In an aphasic or semi stuporous patient this can be done by the so-called feeding test that is, by bringing into the field of vision a spoon on which food has been placed If the patient sees it he will usually open his mouth More accurate determination of the visual field defect is obtained by perimetry or tangent screen studies The optic nerve can be seen directly with the ophthalmoscope, optic atrophy, either primary or secondary, may be detected as well as papill edema

Neurons of the optic nerves arise in the ganglion cells of the retina whence they pass in the optic nerve to the chiasm where the fibers from the temporal half of the retina continue on the same side whereas those from the nasal sides cross The optic tract fibers then terminate in the primary optic centers *i e*, external geniculate body, the pulvinar and the superior colliculus The last neuron in the course of the tract then goes to the occipital pole especially in the region of the calcarine fissure There is no further crossing of the visual pathways so that a lesion involving the optic tract anywhere behind the chiasm will produce contralateral homonymous hemianopsia, or a smaller defect if seen early The fibers for the reflex activity of the pupils run in the optic nerves and are both crossed and uncrossed A lesion anterior to the chiasm results in impairment of vision or in blindness on the same side A lesion at the chiasm such as, for example, that which is seen in pituitary tumors produces a bitemporal hemianopsia due to disturbance of the fibers supplying the nasal halves of the retina

*Binasal hemianopsia* is a rare finding It is due to bilateral lesions usually a syphilitic exudate at the lateral aspects of the chiasm or as a result of pressure from bilateral sclerotic calcification of the internal carotids Lesions in the optic tracts in or anterior to the primary optic centers may readily impair the pupillary reflex Lesions posterior to the primary optic centers do not do so being beyond the reflex arc Lesions deep in the temporal lobe or of the occipital lobes may give a contralateral quadrantanopsia

*The optic nerve may be implicated directly* by tumor syphilis fracture hemorrhage aneurysm or meningitis The nerve itself may be the site of a glioma Direct pressure on the nerve usually results in atrophy If the nerve is involved behind the eyeball the condition is called *retrobulbar neuritis* If

traction and dilatation of the pupil Loss of reaction of the pupil to light occurs in optic atrophy involvement of the third nerve and affections of the ciliary ganglion The loss of the direct reflex to light with preservation of the contraction of the pupils in accommodation for near objects is called the *Argyll Robertson phenomenon* and is a sign extremely suggestive of neurosyphilis It may however be seen in alcoholism arteriosclerosis multiple sclerosis and epidemic encephalitis but is extremely uncommon in those conditions An Argyll Robertson pupil is not necessarily completely paralyzed to light at the beginning but passes through different grades just as any other physical sign The reaction of the pupil to accommodation is the contraction of the pupil which is seen when the patient converges his eyes on a near object The loss of the contraction to accommodation with preservation of the light reflex is occasionally seen in epidemic encephalitis and after diphtheria The *paradoxical pupil* when the pupil dilates instead of contracting on exposure to light is infrequently seen in tabes The ciliospinal reflex which is the reaction of the pupil to painful stimulation of the skin of the neck thereby causing the pupil to dilate is of value in estimating the state of the cervical sympathetic Tonic pupils are found in Adie s syndrome Such pupils do not react to ordinary light but may constrict slightly with bright light The contraction and subsequent dilatation on removing the stimulus is very slow Their reaction to accommodation is markedly delayed Often only one pupil is affected Tonic pupils may be differentiated from the Argyll Robertson type by the fact that they respond normally to the instillation of eserine and homatropine

*Nystagmus* is an involuntary rhythmic tremor of the eyeballs usually bilateral and symmetrical It may be present when the eyeballs are looking straight ahead but is more likely to be developed when the patient looks upward downward or laterally It may be lateral vertical or rotary Nystagmus may be due to cerebellar disease defects in fixation due to extremely poor vision or stimulation of the labyrinths Nystagmus may occur from lesions of the mid brain pons and cerebellum and is frequently seen in such diseases as multiple sclerosis and Friedrich s ataxia Ocular nystagmus in which both phases or the movement are of equal rapidity is a fairly frequent finding in albinism and in patients with high myopia The so-called miner s nystagmus is seen in those who work for long periods in dim light Loss or disturbance of associated movements of the eyes upward or downward is an important localizing sign of disease of the anterior quadrigeminal bodies either directly or by pineal tumors Loss of lateral associated movements in which the eyes cannot be moved to one side is due to a lesion in or near the sixth nerve nucleus or the posterior longitudinal bundle on the side of the paralysis the failure of the opposite internal rectus to function properly is due to the loss of associated movements and not paralysis *Conjugate deviation* is due to loss of power of turning both eyes toward the sides opposite the lesion which is in or above the internal capsule The movements that are not paralyzed draw the eyes toward the side of the lesion

### Fifth Nerve

The trigeminal nerve is a mixed one The motor root supplies the muscles of mastication the tensor tympani tensor palati mylohyoid and anterior belly of the digastric The sensory fibers enter the pons and descend into the cervical cord to the second or third segment The Gasserian ganglion lies in the middle fossa on the petrous portion of the temporal bone The sensory root divides beyond the ganglion into three divisions The *first* or *ophthalmic division* conveys sensation from the eyeball and lachrymal gland the conjunctiva (except that of the lower lid) the skin of the forehead and scalp up to the vertex the mesial part of the skin of the nose and the mucous membrane of the upper part of the nasal cavity

The *second* or *superior maxillary division* conducts sensation from the skin to the upper lip the side of the nose and the adjacent parts of the cheek the lower eyelid and part of the temple It also innervates the conjunctiva of the lower lid the upper

external rectus muscle which moves the eyeball outward

Paralysis of any one of the ocular muscles will lead to double vision and a deviation of the eyeball The diplopia is due to the fact that the image, instead of falling on each retina at the same place, strikes at different points because of the inequality of the muscles Diplopia is present when both eyes are being used, although monocular diplopia, usually an hysterical phenomenon, may occur if a deformity of the cornea is present If the third nerve is completely paralyzed, the upper lid droops because of the paralysis of the levator palpebræ superioris Due to the unopposed action of the external rectus the eyeball is turned outward The eyeball cannot be moved upward, downward or inward, although a slight downward and outward movement can be performed by the superior oblique muscle which is supplied by the fourth nerve Since the third nerve supplies the sphincter of the iris the pupil is wide because of the unopposed action of the dilator which is supplied by the sympathetic The pupil does not respond to light, nor does the eye attempt *convergence* *The third nerve may* be completely paralyzed or partially affected Paralysis of the fourth nerve results in involvement of the superior oblique muscle, which turns the eyeball downward and outward and at the same time rotates the vertical meridian slightly inward at its lower end It is extremely difficult to detect a paralysis of the superior oblique nerve but it is usually determined by the diplopia which results when the patient attempts to look downward and outward The false image stands lower than the true and is especially likely to appear when the patient walks downstairs

The sixth nerve supplies the external rectus and involvement of it produces paralysis of that muscle The patient is unable to turn the eye outward beyond the midline All other movements are normal The diplopia is present when the eyes are directed toward the side of the paralyzed sixth nerve

## The Pupil

The things to be noted about the pupil are the size shape equality position and its reaction to light, to painful stimulation of the skin of the neck and to accommodation Slight inequality (*anisocoria*) may occur in individuals free of disease and, if it is the only abnormality present, may be disregarded If the inequality is considerable *and especially if accompanied by other* signs organic disease may be present The pupils are abnormally large in poisoning by certain drugs such as the atropine group alcohol and cocaine and in individuals who are under emotional stress *Mydriasis* may result from paralysis of the sphincter of the pupil or may be due to stimulation of the dilator The pupils in blind eyes are usually dilated A unilateral fixed dilated pupil may result from compression of the third nerve, by *herniation of the hippocampal* gyrus over the free edge of the tentorium in expanding intracranial lesions *Myosis*, or abnormal smallness of the pupil may occur from disease of the pons in tabes and in cervical cord lesions due to involvement of the cervical sympathetic The pupils may also be contracted as the result of iritis Pilocarpin and opium contract the pupil

The *shape of the pupil* should be carefully determined Unequal and irregular pupils, if *such local conditions as iritis operative* procedures and coloboma have been ruled out, are usually syphilitic in origin although postencephalitic states and cerebral arteriosclerosis are rarely causes of such changes The pupil may be ectopic Occasionally such a condition indicates a lesion of the mid brain Testing of the pupillary reflex to light is an important part of a physical examination Each eye should be tested separately because if the light is thrown in both eyes at the same time a pupil fixed to direct light might react consensually The light reflex depends upon the integrity of the reflex arc The fibers pass in the optic nerves to the *mid brain* and the efferent parts of the arc are made up of the third nerve and ciliary ganglion to the sphincter of the pupil

At times a phenomenon known as *hippus* is found This consists of a rhythmic con

seen in bulbar palsy where only the lower part of the face is involved even though the lesion is in the nucleus because as a usual thing, only the lower part of the nucleus is affected in such cases

### Eighth Nerve

The auditory nerve is composed of the cochlear and vestibular portions Paralysis of the cochlear portion of the nerve results in unilateral deafness The cortical representation of the eighth nerve is in the temporal lobe and the recognition and memory of words heard in the first temporal convolution on the left Involvement of the first temporal convolution will produce a condition known as *word deafness* in which while the patient is able to hear the sound the words are not recognized as such The auditory nerve is frequently pressed upon by tumors may be the seat of a toxic neuritis and may be involved in syphilis at the base, in meningitis or by any acute infections and it may be infiltrated in leukemia Hemorrhage or inflammatory reactions in the labyrinths may occur in any toxic or infectious state In a patient suffering from diminution or loss of hearing it is important to differentiate between nerve deafness and the deafness which arrives as a result of middle ear disease The differential diagnosis is made by a careful neurologic examination and the use of Weber s Rinne s and Schwabach's tests Tumors of the eighth nerve are common Involvement of the vestibular portion of the eighth nerve is exemplified by Meniere s disease or more properly *Meniere s syndrome*

Syphilis arteriosclerosis malaria and almost any infection or toxemia are capable of producing changes in the labyrinth Acute involvement of the labyrinth produces vertigo vomiting disturbance of the equilibrium and of the gait and pronounced nystagmus Any movement of the patient produces vertigo so intense that the patient may be thrown to the ground like a bolt Tinnitus and impaired hearing or even deafness are present and usually remain after the other symptoms have disappeared Diarrhea may also occur during an attack of acute labyrinthitis Tumors in the angle and syphilis of the base should always be excluded when Meniere s syndrome presents itself The acute attack may clear up, to be followed by signs of chronic labyrinthitis which is also often due to middle ear disease The symptoms may vary from tinnitus and slight deafness and vertigo to dizziness so intense that the patient is thrown to the ground The relief of these symptoms is very difficult Intracranial section of the vestibular branch of the eighth nerve has been recommended Meniere s syndrome is occasionally mistaken for epilepsy, but the dizziness deafness and tinnitus unaccompanied by unconsciousness which is rarely present should make the differentiation possible

### Ninth Nerve

Involvement of the glossopharyngeal nerve rarely occurs by itself If it should happen the symptoms would be loss of taste over the posterior third of the tongue dysphagia, loss of the pharyngeal reflexes and anesthesia in the upper portion of the pharynx

Glossopharyngeal neuralgia, a rather rare condition, is characterized by transient paroxysms of excruciating pain referred to the ear the tonsillar region pharynx or side of the neck These attacks are often brought on by swallowing or yawning A trigger zone probably exists in the Eustachian tube

### Tenth Nerve

Paralysis of the vagus nerve may be part of the symptom complex of bulbar palsy tumors of the bulb acute and chronic inflammations syringomyelia and multiple sclerosis The vagus nerve is occasionally acutely inflamed especially after attacks of diphtheria It is also involved though infrequently by poisons such as alcohol After the nerve emerges from the bulb it may be involved by neoplasms inflammatory reactions of the meninges vascular disease especially aneurysms and disease of the base of the skull It is occasionally injured during operations on the neck The recurrent laryngeal branch of the nerve may be cut during an operation on the thyroid and is frequently paralyzed by an aneurysm of the

teeth the mucous membrane of the upper lip, the upper part of the cheek, upper jaw, hard palate, uvula, tonsil naso-pharynx, middle ear and the lower part of the nasal cavity

The *third*, or *inferior maxillary division* contains, in addition to sensory fibers the motor root The sensory part of the nerve supplies the skin of the posterior part of the temple and the adjacent part of the pinna the anterior and the upper wall of the external auditory meatus, part of the cheek, the lower lip and chin the lower teeth and gums part of the tongue the floor of the mouth the inner surface of the cheek and the salivary glands

The taste fibers from the anterior two thirds of the tongue are contained in a branch of the third division They leave the lingual branch course along the chorda tympani and reach the facial nerve in the Fallopian aqueduct The taste fibers from the posterior third of the tongue are supplied by the glossopharyngeal nerve The tongue is tested in the anterior and posterior parts separately Substances such as quinine, vinegar, sugar and salt are used and are rubbed on the tongue With his tongue out the patient should be asked whether the substance is sweet salty bitter or sour and he should communicate his opinion to the examiner by a nod of the head Loss of taste is called *ageusia* The important reflexes in the domain of the fifth nerve are the corneal sneeze and conjunctival The *corneal reflex* is elicited by touching the cornea with a probe padded with cotton or with the head of a pin Care should be taken not to touch an eyelash or to bring the testing object over the pupil, because in either event the patient will blink Both corneal reflexes are lost in anesthesia and coma The sensory part of the arc is the fifth nerve and the motor part is the seventh If the corneal reflex is lost from a lesion of the fifth nerve neither eye will blink If the reflex is lost from a lesion of the seventh nerve the pain produced by the corneal contact will cause the other eye to blink Loss of the corneal reflex is the earliest sign of involvement of the sensory part of the fifth nerve The *conjunctival reflex* is taken in much the same way except the conjunctiva is touched rather than the cornea The *sneeze reflex* is tested by irritating the nasal mucous membrane with a probe padded with cotton The normal individual or the hysteric whose fifth nerve is intact, will sneeze If the motor root is paralyzed the temporal fossa is hollowed and the masseter wastes When the patient is instructed to close his mouth the affected muscles do not harden under the examiner s fingers When the patient opens the mouth the jaw is pushed toward the paralyzed side This occurs because the external pterygoid fails to draw the condyle forward on the affected side Trophic disorders may occur on the side of a fifth nerve paralysis the secretion of tears of saliva and of nasal mucus is diminished and thereby the functions of those parts are interfered with The teeth may become loose on the side of the trophic lesion and fall out Neuroparalytic keratitis may occur on the affected side Facial hemiatrophy and hypertrophy are thought by some to be due to trophic lesions of the fifth nerve but removal of the Gasserian ganglion has not been known to produce hypertrophy or atrophy of the face

## Seventh Nerve

The facial nerve supplies all the muscles of the face with the exception of the levator palpebræ superior, down to and including the platysma The nerve contains the taste fibers of the chorda tympani and deep pressure pain fibers for the face The nerve is frequently paralyzed by infections exposure to cold, tumors of the parotid middle ear disease tumors of the cerebellopontile angle and syphilis in the angle Two types of *facial paralysis* are to be distinguished In peripheral facial palsy due to involvement of the peripheral nerve or nucleus the entire side of the face is involved The patient is unable to close his eyes wrinkle his forehead smile whistle or puff his cheeks In a central facial palsy due to a lesion of the pyramidal tract the upper part of the face is unaffected but in showing the teeth or smiling a weakness is noted on the affected side Sometimes a normal facial asymmetry may be mistaken for a slight central facial palsy An exception to the above rule is

tained On the other hand if the stimulation is too great a mass of reflexes will occur from which nothing can be learned It is frequently necessary to attract the patient's attention while this reflex is being taken Occasionally the reflex may be obtained when the skin of the heel is irritated or by drawing a pin across the ball of the foot In the person with an intact pyramidal system the great toe flexes If the pyramidal tract or the leg center in the cortex is affected by disease or injury the great toe extends The more slowly and more isolated the extension is the more typical is the reflex There may be other movements of the toes such as flexion extension or fanning but it is the movement of the great toe which distinguishes the reflex The extensor plantar reflex (Babinski's sign) is always pathologic except in infants whose pyramidal tracts are not yet myelinated and means interruption in some degree at least of the functions of the pyramidal tract The abnormal plantar reflex may occur after an epileptic fit and in uremia diabetes or alcoholism There are many modifications of the Babinski reflex such as the Oppenheim Chaddock and Gordon reflexes all of which mean the same The Babinski *reflex has done a great deal to differentiate* between organic and hysterical conditions If the plantar reflex arc is interrupted for example by loss of sensation or by a peripheral paralysis of the flexors of the toes no plantar response will be obtained

In the upper extremity a reflex somewhat comparable in its significance to the Babinski reflex has been described by Tromner and by Hoffman With *the patient's forearm* and hand midway between pronation and supination the left hand of the examiner supports the forearm and the nail of the middle finger is slightly stroked and flicked toward the palm If the pyramidal tract is normal the thumb or index finger does not move but if the pyramidal fibers are involved the thumb and index finger approach each other and the distal phalanx of the index finger or thumb or both move in flexion This reflex does not have the specific pathognomonic significance of Babinski's sign the sign may appear and disappear in some patients who have been observed for years without showing any other evidence of organic neurologic disease It is not infrequently *found* in neurotics especially in those with marked anxiety and muscular tenseness along with hyperreflexia

The *abdominal reflexes* appear after the pyramidal tracts are myelinated They are normally present except in the obese and in those whose abdominal walls are relaxed and atonic for any reason the most important of which is pregnancy The loss of the reflex is common in acute abdominal conditions It is obtained by stroking the skin of the abdomen parallel with Poupart's ligament and the costal border Any blunt object may be used but a pin produces best results The reflexes are called the upper and lower and the segments of the cord concerned are the eighth to the twelfth dorsal The reflex consists of a dimpling or a pulling of the skin and movement of the umbilicus toward the stroked side due to contraction of the abdominal recti muscles In a healthy individual with normal abdominal walls loss of reflex means an interruption in the reflex arc such as might occur for instance in anterior horn disease It may also be due to involvement of the pyramidal tract and is therefore a frequent sign of hemiplegia In the presence of other signs the absence of abdominal reflexes in a young individual is suggestive of multiple sclerosis The abdominal reflexes are lost on the paralyzed side if the pyramidal tract lesion is above the eighth dorsal segment

The *cremasteric reflex* is obtained by stimulating the skin of the upper and inner *side of the thigh which produces an elevation* of the testicle on that side Its loss has the same significance as the abdominal reflex The segments in the cord concerned with this reflex are the first and second lumbar

The important *deep reflexes* (sometimes called tendon) are the patellar Achilles triceps and biceps Complete relaxation of the muscles concerned in a reflex must be obtained and the reflexes that are not obtainable while the patient is in bed should if possible be tested when the patient is up before they are considered lost Involvement of either the sensory or motor component of the arc will cause a diminution or

aorta, by dilatation of the left auricle such as occurs in mitral stenosis and by neoplastic masses in the mediastinum Paralysis of the tenth nerve produces unilateral paralysis of the palate, pharynx and larynx which produces a nasal quality of the voice and slight dysphagia The soft palate is immobile and is lower than normal and the palatal and pharyngeal reflexes are absent The homolateral vocal cord is in the so-called cadaveric position, and fails to move during phonation and respiration The cardiac rate and rhythm are not altered and abdominal symptoms are usually absent Bilateral recurrent paralysis is usually central in origin and causes complete loss of voice, respiration is difficult stridor and dyspnea are usually pronounced and there is lack of closure of the glottis in coughing Involvement of the tenth nerve is often associated with implication of the ninth eleventh and twelfth

### Eleventh Nerve

The spinal accessory nerve is a motor one consisting of two parts, the medullary and spinal The bulbar part of the nerve is really part of the vagus The eleventh nerve supplies the sternomastoid and the trapezius In general, it is affected by the same things which cause involvement of the ninth and tenth nerves and also by affections of the upper cervical cord It is not infrequently cut during operations on the neck The paralysis of the nerve produces inability to turn the head toward the opposite side and the head deviates to the affected side when the chin is forced downward against resistance Involvement of the trapezius produces a drooping of the shoulder on the paralyzed side, alteration of the outline of the neck, shrugging of the shoulder is interfered with, and the scapula cannot be brought to the midline The scapula is displaced down and out The affected muscles are atrophic and show alterations to the electrical reactions

### Twelfth Nerve

The hypoglossal nerve is a motor nerve supplying the muscles of the tongue The tongue is usually involved in ordinary cases of hemiplegia, in which it deviates to the side of the paralysis, on protrusion It does this because of the action of the uninvolved glossal muscle which pushes the tongue out and toward the opposite side It is practically always involved in bulbar palsy and is vascular and inflammatory reactions in the bulb Tumors of the bulb and the diseases of the spinal cord especially amyotrophic lateral sclerosis and syringomyelia, may be complicated by involvement of the twelfth nucleus Syphilis of the bulb or at the base of the brain may implicate the twelfth nerve Nuclear disease such as is produced by bulbar palsy, is practically always bilateral Outside of the skull the nerve may be involved by malignant disease trauma, disease or injury to the atlas and aneurysm of the carotid artery The affection of the nerve produces a paralysis of the tongue on the side of the lesion The tongue appears wrinkled and atrophic the electrical reactions are reversed and fibrillary tremors are usually pronounced although they may be absent in peripheral involvement If only one twelfth nerve is paralyzed the ability to eat is not affected but, if the tongue is paralyzed on both sides eating is difficult and speech which is also little affected by unilateral paralysis is seriously involved

## THE REFLEXES

The examination of the reflexes is a necessary part of each neurologic survey of an individual One of the most important is the *plantar reflex* which with the abdominal and cremasteric make up the important superficial reflexes To obtain the plantar reflex the patient should be recumbent the foot should be warm externally rotated and grasped firmly at the ankle by one of the examiner s hands The sole of the foot should then be stimulated at the junction of the outer and middle thirds beginning at the heel and going forward Practically any small object may be used, but the best is a pin The least amount of stimulation necessary to bring about a response should be employed If too light stimulation is used no reaction whatsoever will be ob

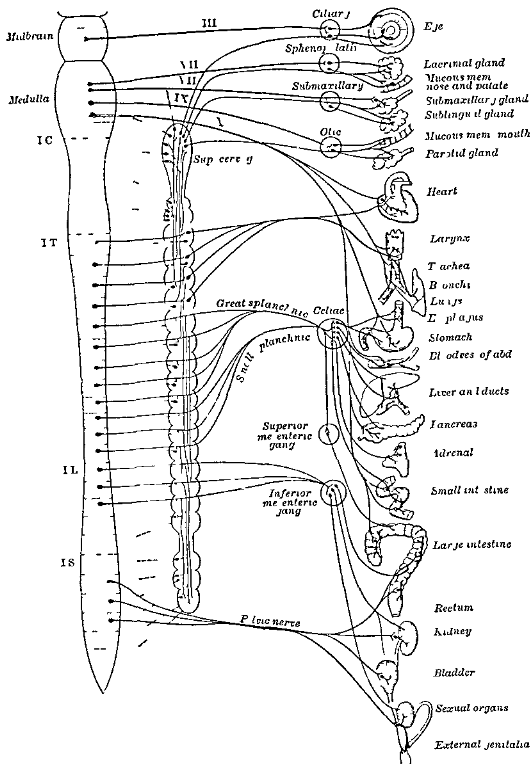

Diagram of efferent autonomic nervous system Blue cranial and sacral outflow parasympathetic Red thoracolumbar outflow sympathetic ----- Postganglionic fibers to spinal and cranial nerves to supply vasomotors to head trunk and limbs motor fibers to smooth muscles of skin and fibers to sweat glands (Modified after Meyer and Gottlieb) This is only a diagram and does not accurately portray all of the details of distribution *

* Manifestations due to disturbance in the autonomic system are discussed in the pertinent sections For a brief presentation of the manifestations due to involvement of the sympathetic and parasympathetic system the reader is referred to Frank L Apperly Patterns of Disease on the Basis of Physiologic Pathology J B Lippincott Co 1951 p 395 Editor

disappearance of the reflex. Thus, lesions of the peripheral nerves, of the spinal roots, of the posterior and anterior horns will cause a *diminution or loss of the deep reflex* at the level of the lesion. Involvement of the anterior horn cells of the cervical cord will not, of course, affect the reflexes of the lower extremities. A reflex may also be lost because of disease of the muscles, as in muscular dystrophy, where the reflex disappears as the muscle atrophies. The deep reflexes are exaggerated in disease of the pyramidal tracts, in functional nervous disorders, especially hysteria, and in cases where anxiety is a prominent symptom, in disease of the joints, after exercise, and in stimulation of the nervous system from the excessive use of tea, coffee and alcohol. It is only in disease of the pyramidal tract, however, that the Babinski sign occurs. A generalized increase in the deep reflexes without Babinski's sign or ankle clonus is not of nearly as much importance as the diminution, loss or inequality of the reflexes.

The *biceps reflex* is obtained by tapping the biceps tendon. The *triceps reflex* is obtained by striking the triceps tendon.

The best position in which to obtain the *patellar reflex* is to have the patient sitting in a chair with the feet flat on the floor. The patellar tendon should then be located, one of the examiner's hands placed on the thigh while the other wields the hammer which should strike the tendon a sharp, quick blow. If the reflex is difficult to obtain or is diminished, it may be brought out by reinforcement. In the case of the patellar reflex this may be done by having the patient squeeze his hands at the count of three, or better yet, by having him press downward with the ball of his foot as the patellar tendon is tapped. The *Achilles reflex* is obtained by having the patient kneel on a chair with the feet hanging over the seat, or by having him rest his hands on a desk or chair while flexing one leg off the floor. The examiner supports the foot at the ankle and taps the tendon of Achilles. A jar may be misinterpreted as a reflex.

The segments with which the important deep reflexes are concerned are as follows:

Biceps, fifth and sixth cervical.
Triceps, sixth and seventh cervical.
Patellar, second to fourth lumbar.
Achilles, fifth lumbar, first and second sacral segment.

*Ankle clonus*, which is frequently seen in pyramidal tract disease, and which consists of a rhythmic contraction of the soleus muscle, is obtained by having the knee moderately flexed. The examiner then sharply extends the foot, exerting pressure on its ball. A pseudoclonus may occasionally be found in hysteria.

The *vegetative* or *visceral reflexes* (vesical, rectal and genital) are due in most part to contraction of involuntary muscles; their centers are in the sacral cord, below the third sacral segment, and in the sympathetic nervous system. The *cilio spinal reflex*, which is brought out by pinching the skin of the neck, consists in a dilation of the pupil *on the ipsolateral side, and is due to stimulation of the cervical sympathetic*. Pressure backward on the eyeballs produces the *oculo-cardiac reflex* by which the rate of the pulse is slowed. (Plate 10.)

## THE MOTOR SYSTEM

Involvement of the motor system produces loss of or impaired power. The patient will often indicate where the weakness or paralysis exists. All of the muscles should be tested against resistance and the power of the hands should be determined with a dynamometer. An apparent loss of power may occur in hysteria, and power may be weak in the presence of muscles apparently splendidly developed, such as occurs, for example, in pseudohypertrophic muscular dystrophy. To examine properly the muscular system the individual muscles should be observed and palpated. It should be noted whether or not the muscles are normal, flabby or atrophic.

Atrophy of the muscles may be due to lesions of the peripheral motor nerve, anterior root, anterior horn cells, disease of the muscles themselves (such as dystrophy), bone and joint disease and wounds of an extremity, which produce the so-called muscular reflex atrophy. Atrophy of muscles rarely occurs from a cerebral lesion except in lesions of the parietal lobe; the *atrophy* is on the contralateral side of the lesion, is not severe and must be differentiated from wasting produced by disuse and ankylosis.

of joints Lesions of the motor peripheral nerve produce a flaccid atrophic paralysis with loss of reaction to faradism and equalization or reversal of the polar reactions in galvanism The deep reflexes in the distribution of the paralysis are lost or decreased Fibrillary tremors occur in the atrophic muscles if the lesion is in the anterior horn cells occasionally does an involvement of the peripheral nerve produce this phenomenon Fibrillary movements of the muscles are of great significance if they occur with other signs of organic disease It is a common symptom in the tongue in bulbar palsy and in muscles wasting from anterior horn disease Fibrillary tremors or muscle quivering are also seen in neurasthenic, poorly nourished individuals and in those who take tea, coffee alcohol or tobacco to excess In such instances the tremors are especially common in the deltoid biceps the large muscles of the thighs and of the eyelids Anterior horn symptoms always occur at the level of a lesion The atrophy which occurs in bone or joint disease is usually limited to a segment of the extremity involved but it may implicate the entire extremity The neighborhood deep reflex may be increased but Babinski s sign fibrillary tremors and reactions of degeneration do not occur If the joint disease is bilateral and produces reflex atrophy the case may be mistaken for amyotrophic lateral sclerosis A lesion of the anterior root will simulate closely that due to involvement of the anterior horn with one important exception fibrillary tremors are not present

*Paralysis* means a loss of power due either to functional or structural interruption in any part of the motor path and including the muscle itself *Paresis* means a weakness The two are often used rather loosely The term paralysis is often incorrectly employed when partial loss of power is meant

Paralysis of a mixed nerve will produce both motor and sensory loss To recapitulate a lower motor neuron disease produces flaccid paralysis of muscles supplied by the nerve anterior root or anterior horn cells and later atrophy develops The local deep reflex is lost and the response to faradism is absent Galvanism response is slow and with a reversal of the polar reactions Fibrillary tremors occur in anterior horn disease but not as a rule, in disease of the peripheral nerves

The *tone of an extremity* weakened or paralyzed by involvement of the voluntary motor pathway anywhere in its course from the motor cortex to the lower part of the cord is usually increased The paralysis or weakness which occurs is below the level of the lesion if this is above the decussation in the bulb, the paresis is on the contralateral side Below the pyramidal decussation the weakness which ensues is on the side of and below the lesion If both pyramidal tracts are involved above the decussation the condition is referred to as *diplegia* A lesion in an internal capsule produces weakness or paralysis of the opposite side, face arm and leg (*hemiplegia*) A complete lesion of the spinal cord in the cervical cord will produce *tetraplegia* or as it is called by some *quadriplegia* Implication of both pyramidal tracts of the spinal cord below the second dorsal will produce a *crural paraplegia* Paralysis of both upper extremities from a cord lesion is referred to as a *brachial paraplegia* and though rare may occur for example from acute anterior poliomyelitis or from occlusion of the anterior spinal artery

Paralysis of one extremity called *monoplegia* is the result of a cerebral spinal or peripheral lesion or of hysteria If part of an extremity is paralyzed as the result of a cerebral lesion the condition has been called by Spiller *segmental monoplegia* In pyramidal tract disease, particularly in cortical involvement movements and not muscles are paralyzed The deep reflexes are increased and various types of clonus may be elicited such as ankle patellar or wrist clonus The plantar reflex is of the extensor or Babinski type The muscles do not become atrophic from upper motor neuron palsy, but atrophy may develop if ankylosis of a joint or arthritis occurs on the paralytic side The muscles react normally to electricity In progressive pyramidal tract involvement with total paralysis especially in cases in which the cord has been injured or is pressed upon from without for example by Pott s disease

tempting the finger to nose test the patient overshoots the mark producing a symptom called *hypermetria* If a vertical line is drawn on a sheet of paper and the patient tries to draw a series of horizontal lines to the vertical line he overshoots or under shoots the mark The *rebound phenomenon of Holmes* is elicited in the following manner if an attempt is made by the examiner to extend the forearm against resistance and the force is suddenly discontinued the hand rebounds unchecked against the shoulder Another characteristic symptom of cerebellar disease is *adiadokokinesis*, which means a loss of the ability rapidly to perform a movement which calls into play antagonistic groups of muscles This symptom is elicited by having the patient rapidly pronate and supinate his hands or slap his palms and the extensor surfaces of the hands alternately against his knees In cerebellar disease, the patient performs these movements in an incoordinate fashion Cerebellar catalepsy is a very rare symptom It should be emphasized that there is no loss of sensation and no loss of power in the sense that it occurs in upper or lower motor neuron disease

*Cerebellar fits*, originally described by Hughlings Jackson are tonic in type and in reality the picture of decerebrate rigidity is produced Cerebellar fits due to involvement of the vermis, are bilateral those due to involvement of one of the cerebellar lobes are unilateral and on the side of the lesion

## Gait

Although all disturbances of gait are not exclusively due to involvement of the motor system they will be discussed under that heading

In testing a patient s gait he should be told to walk across the room preferably in a straight line and to turn sharply and walk back In spastic crural paraplegia the lower extremities are moved stiffly the steps are short the toes are scraped along If there is pronounced adductor spasm the so called scissor gait occurs in which the feet are alternately placed one in front of the other This gait may also be seen in bilateral cerebral lesions In a spastic gait occurring in paraplegia the soles of the shoes at the toe are worn off long before the rest of the shoes and the uppers are scuffed at the toes due to catching those parts in going upstairs In the hemiplegic gait the lower extremity on the affected side is swung from the hip the joints are flexed little or not at all and the anterior part of the foot is scraped on the ground In addition the upper extremity is held in a characteristic attitude The steppage or high stepping gait is that which occurs in a patient suffering from foot-drop, due especially to lesions of the anterior horns or the peripheral nerves and occurring in its best illustration in multiple neuritis and poliomyelitis A lesion of one popliteal nerve may produce a unilateral steppage gait In the steppage gait, the extensors of the toes and feet being paralyzed the patient must raise the knees high to make the toes and feet clear the ground and, as the feet come down they make a flip-flop sound due to the striking of the anterior part of the foot first and the heel second The gait of muscular dystrophy produces the duck or waddling gait quite similar to that seen in double congenital dislocation of the hips In this gait the feet are more widely separated than normally and a distinct lordosis occurs The ataxic gait is seen in tabes dorsalis in some patients with multiple neuritis and in any condition which involves the posterior columns such as the combined sclerosis of pernicious anemia The patient s walking base is widened, he lifts the feet jerkingly and suddenly throws them too wide and too high and then stamps the heels to the ground An ataxic gait can be told not only by sight but also by hearing since he makes a very characteristic stamping noise as he walks To re-enforce his faulty position sense his eyes are glued to the ground he has difficulty in walking a straight line and in proceeding with the eyes shut in the dark or backwards When the pyramidal tracts and posterior columns are both involved in the same patient for example in the combined sclerosis of pernicious anemia the gait assumes an element of both spasticity and ataxia A reeling or drunken gait is significant of cerebellar disease and if the cerebellar involvement is unilateral the patient has a

or a tumor, the reflexes of defense or spinal automatism may occur Thus, in a totally paralyzed extremity, even in one in which sensation may be completely abolished, sharply flexing the toe (*Strümpell's phenomenon*) or irritating the extremity up to a level corresponding to the height of the lesion will cause the paralyzed extremity to be sharply withdrawn That is, the foot and toe are extended and the knee and hip flexed This may be mistaken for a voluntary movement, especially if the idea is entertained that the patient is hysterical It is a bad prognostic omen, unless the cause can be removed, and is not a sign of returning power

If the pyramidal tract fibers to an extremity *are completely obliterated*, by a complete transection of the spinal cord, there is a flaccid paralysis of the extremity below the lesion with a loss of the deep reflexes and a plantar reflex of the flexor type or the plantar reflex may be absent, the so-called *Bastian's law* This is seen in its most typical form in paralysis coming on suddenly as the result of injury It may, however, be due to disease

Paralysis may be crossed, that is part of *the paralysis is on one side of the body* and part on the other due to a single lesion for example, a lesion in the right cerebral peduncle will produce a third nerve palsy on the side of the lesion and implication of the face, arm and leg on the opposite side (*Weber's syndrome*) *If in addition, there is* a tremor of the weak or paralyzed side of the body, it is referred to as *Benedikt's syndrome* The third nerve fibers the pyramidal tract and the red nucleus are implicated A lesion in the pons at the level of the facial nucleus will bring about facial paralysis of the peripheral type on the side of the lesion and of the arm and leg on the contralateral side Usually the ipsilateral *sixth nerve* is also involved giving rise to an internal strabismus on the side of the lesion (*Millard-Gubler syndrome*) A crossed sensory paralysis may occur in occlusion of the posterior inferior cerebellar artery with a loss of pain, heat and cold on the side of the face corresponding to the lesion and on the opposite side of the body

The increased tone in pyramidal tract disease is supposed to be due to release of the cortical inhibition Increased tone, even rigidity, may be seen in lesions of the extra pyramidal system The most intense rigidity which one of the writers has ever seen was in a case of bilateral lenticular degeneration *due to carbon monoxide poisoning* all of the joints including the jaws were so stiff that it was impossible *to move* them Despite the intense rigidity in such cases Babinski's sign is not present If the increased tone, however, is accompanied by an irregular movement such as chorea or athetosis, extension of the great toe may occur coincidentally as the foot is stimulated The extra pyramidal system when involved, produces in addition to *rigidity some type of irregular movements* as choreiform movements and athetosis In paralysis agitans the rigidity is of the cog wheel variety, and automatic movements such as blinking and the swinging of the arms in walking are lost or impaired

A combination of upper and lower motor neuron disease may occur in the same individual thus disease or injury to the cervical cord may produce paralysis of the anterior horn cells with resulting signs at the level *of the lesion Implication of the pyramidal* tracts at the same time will produce a spastic paralysis below this is not an uncommon finding in syringomyelia Involvement of the lumbosacral cord will cause a *flaccid* atrophic paralysis at the level of the lesion *Disease of the muscles themselves* such as occurs in progressive muscular dystrophy produces weakness and ultimately paralysis of the affected parts The nervous system is intact in this disease There are no sensory losses and the reflexes and electrical reactions disappear with the muscles Certain muscles especially the deltoids and those of the calves may be the site of pseudo *hypertrophy*

Involvement of the cerebellum or its tracts does not produce disturbance of sensation but causes *incoordination* The *function of the cerebellum is to coordinate* and to make even and smooth voluntary motor impulses This makes for *synergic movements* If this element is lacking the movement becomes jerky, ataxic and asynergic The movements are not synchronized and occur separately and disjointedly At

tempting the finger to nose test the patient overshoots the mark, producing a symptom called *hypermetria* If a vertical line is drawn on a sheet of paper and the patient tries to draw a series of horizontal lines to the vertical line he overshoots or undershoots the mark The *rebound phenomenon of Holmes* is elicited in the following manner if an attempt is made by the examiner to extend the forearm against resistance and the force is suddenly discontinued the hand rebounds unchecked against the shoulder Another characteristic symptom of cerebellar disease is *adiadokokinesis* which means a loss of the ability rapidly to perform a movement which calls into play antagonistic groups of muscles This symptom is elicited by having the patient rapidly pronate and supinate his hands or slap his palms and the extensor surfaces of the hands alternately against his knees In cerebellar disease the patient performs these movements in an incoordinate fashion Cerebellar catalepsy is a very rare symptom It should be emphasized that there is no loss of sensation and no loss of power in the sense that it occurs in upper or lower motor neuron disease

*Cerebellar fits* originally described by Hughlings Jackson are tonic in type and in reality the picture of decerebrate rigidity is produced Cerebellar fits due to involvement of the vermis are bilateral those due to involvement of one of the cerebellar lobes are unilateral and on the side of the lesion

## Gait

Although all disturbances of gait are not exclusively due to involvement of the motor system they will be discussed under that heading

In testing a patient s gait he should be told to walk across the room preferably in a straight line and to turn sharply and walk back In spastic crural paraplegia the lower extremities are moved stiffly the steps are short the toes are scraped along If there is pronounced adductor spasm the so called scissor gait occurs in which the feet are alternately placed one in front of the other This gait may also be seen in bilateral cerebral lesions In a spastic gait occurring in paraplegia the soles of the shoes at the toe are worn off long before the rest of the shoes and the uppers are scuffed at the toes due to catching those parts in going upstairs In the hemiplegic gait the lower extremity on the affected side is swung from the hip the joints are flexed little or not at all and the anterior part of the foot is scraped on the ground In addition the upper extremity is held in a characteristic attitude The steppage or high stepping gait is that which occurs in a patient suffering from foot-drop due especially to lesions of the anterior horns or the peripheral nerves and occurring in its best illustration in multiple neuritis and poliomyelitis A lesion of one popliteal nerve may produce a unilateral steppage gait In the steppage gait the extensors of the toes and feet being paralyzed the patient must raise the knees high to make the toes and feet clear the ground and as the feet come down they make a flip flop sound due to the striking of the anterior part of the foot first and the heel second The gait of muscular dystrophy produces the duck or waddling gait quite similar to that seen in double congenital dislocation of the hips In this gait the feet are more widely separated than normally and a distinct lordosis occurs The ataxic gait is seen in tabes dorsalis in some patients with multiple neuritis and in any condition which involves the posterior columns such as the combined sclerosis of pernicious anemia The patient s walking base is widened he lifts the feet jerkingly and suddenly throws them too wide and too high and then stamps the heels to the ground An ataxic gait can be told not only by sight but also by hearing since he makes a very characteristic stamping noise as he walks To re-enforce his faulty position sense his eyes are glued to the ground he has difficulty in walking a straight line and in proceeding with the eyes shut in the dark or backwards When the pyramidal tracts and posterior columns are both involved in the same patient for example in the combined sclerosis of pernicious anemia the gait assumes an element of both spasticity and ataxia A reeling or drunken gait is significant of cerebellar disease and if the cerebellar involvement is unilateral the patient has a

tendency to veer toward the side of the lesion

The variety of gait frequently seen in elderly people with multiple areas of cerebral softening is the gait of "little steps" in which the patient takes short quick steps, often with evidence of spasticity on one or both sides Patients suffering from marked chorea, either Sydenham's or Huntington's but especially the latter, have a peculiar bizarre gait, which is caused by the irregularly appearing choreiform movements in the muscles of the lower extremities the pelvic girdle and the trunk This causes the patient to sway or pitch now to one side, now to the other, or perhaps forward The gait and also the posture of Parkinson s disease is characteristic The upper extremities are flexed at the elbows wrists, arms and hands which are held in the writing position The trunk and neck are flexed Often as he arises from a chair and before he is started in walking he takes involuntary steps laterally or backward When he is fairly well advanced in the disease he then shows the shuffling festinating gait which is so significant of the illness As he walks, the gait becomes faster and faster the patient appears to be pushed forward until finally he has to grasp hold of something so that he may stop and rest No matter how marked the festination it is unusual for a person with paralysis agitans to fall

In testing the gait much can be learned, not only from the manner in which the patient walks but also from the ease and facility with which he turns because in turning the first disturbance in gait may be seen The gaits of hysteria are many and varied *Astasia abasia* is used to describe that symptom of hysteria in which a patient capable of moving the lower extremities can neither stand nor walk In hysterical hemiplegia the affected foot is pushed or dragged along and rigidity of the joints or scraping of the foot along the floor is not found as it is in organic hemiplegia Hysterical disturbances of gait may be grafted upon an organic disease A person with hysterical disturbance of gait can often, by suggestion be made to walk much better backward than forward, whereas all organic gaits are made worse by walking backward

Involvement of the middle lobe or vermis of the cerebellum produces in the gait a tendency to fall forward or backward and often the asynergia of the trunk muscles is so great that it is impossible for the patient to walk at all

Involuntary and irregular movements are usually indicative of basal ganglia disorders and are seen in paralysis agitans progressive lenticular degeneration athetosis chorea, spasmodic torticollis

*Myoclonus* is a shock like contraction of the muscles occurring at regular or irregular intervals and varying from two or three a minute to one almost every second This is a common symptom in epidemic encephalitis The abdominal muscles especially are involved *Hiccough* is a myoclonic contraction of the diaphragm due to excitation of the inspiratory center Hiccoughing is a common symptom in encephalitis, but may be a result of other toxemias or occur reflexly from visceral disturbances

## Tremor

Tremor may be defined as an involuntary rhythmic movement of a part of the body, resulting from the contraction of muscle groups Tremors may be simple, in which only a single muscle group is involved, or may be compound where several muscle groups are affected They may be rapid or slow and may be increased or diminished by action Like all other involuntary movements they stop during sleep Tremors may be seen in exophthalmic goiter alcoholism and with excessive use of tobacco tea and coffee Emotional excitement especially fear may produce a generalized simple tremor Senile tremor may resemble closely that of Parkinson's disease but usually occurs bilaterally from the onset the rigidity of Parkinson s disease is absent This tremor is usually not affected or increased by action A senile tremor also affects the head and face more than the usual paralysis agitans tremor In some individuals a tremor of the head speech and upper extremities seems to be hereditary Tremors of the head accompanied by nystagmus may occur in poorly nourished rachitic children (spasmus nutans)

## SENSATION

Much may be learned about the sensory condition of a patient with no other instrument than a pin and even test tubes of hot and cold water may be needless luxuries Testing of sensation is the most trying part of a neurologic examination and it is imperative that both the examiner and the patient be free of fatigue and irritation The best time to do a sensory examination is early in the morning Outside distractions should be prevented the room in which the examination is made should be warm interruptions should not be allowed and the patient himself should be warm relaxed and in the recumbent position To diagnose and to localize lesions which cause sensory changes it is necessary to understand the pathways by which the sensory tracts ascend Most of the peripheral nerves are mixed and involvement of them produces in addition to paralysis loss of sensation which will of course correspond to the distribution of the particular nerve involved If all of the nerves of an extremity are involved the sensory loss is always most marked in the distal segment of the extremity and all forms of sensation are involved It is rarely that a dissociation sensory loss occurs from a lesion of a peripheral nerve but such a thing occasionally occurs in postdiphtheritic multiple neuritis In this condition however there is a possibility that the posterior columns of the cord may be affected The sensory fibers pass into the posterior roots and thence to the cord Involvement of a posterior root produces irritative sensory phenomena in the distribution of that particular root This is the nature of a pain usually of the sharp cutting type so common in tabes dorsalis The *pain is increased by sneezing coughing* or jarring and if it occurs in the chest it is often mistaken for pleurisy or angina If it is in the abdomen it is frequently thought to be appendicitis or some other acute abdominal condition and if it occurs in an extremity it is called neuritis rheumatism or sciatica As the root becomes more involved a loss of sensation occurs The form of sensation lost earliest and most frequently is *pain* so that in time the patient has an area in which he has a great deal of pain but in which pain sense itself is diminished delayed or lost The painful areas referred to the skin due to posterior root involvement may be small and of the so-called spot variety which are common in tabes dorsalis When the root enters the spinal cord the fibers relaying sensation from the muscles tendons joints and bones all the so-called gnostic sensations enter the posterior columns and ascend uncrossed to the gracilis and cuneate nuclei on the ipsolateral side of the medulla Shortly afterward the fibers cross the midline in the internal arcuate fibers thus forming the sensory decussation of the fillet They then pass through the crus to the optic thalamus where the fibers are again separated most of them end in the thalamus and some continue to the postrolandic area

*Deep pressure pain* is obtained by pressing on an area until the patient complains of pain or discomfort *Touch* in ordinary practice can be tested with the examiner's finger which should be stroked as lightly as possible on the area to be tested a wisp of cotton a camel hair brush or a feather may also be used *Heat* and *cold* are usually tested by test tubes filled with hot or cold water and the tubes applied in an irregular manner to the skin In all sensory examinations the patient should be blindfolded or should not be permited to see what is going on The sense of position or joint or posture sense is tested by moving passively a joint into various positions The part being moved should be grasped laterally For example if the sense of position being tested in the toe it should not be pushed upward or downward but should be grasped on either side and pulled in the desired direction This is important because a patient may have disturbance in the sense of position but if other forms of sensibility are normal he will be able to appreciate that his toe is pushed upward or downward When the member being tested is placed in a position the patient is then asked to describe the position in which it has been placed

Vibratory sense is tested by means of a tuning fork 128 C which having been set into vibration is placed upon a bone The normal patient says he feels a thrill

whereas the one with loss of vibratory sense feels nothing *Stereognosis* is the ability of an individual to recognize an object placed in the hand, by appreciation of its weight, size shape or texture Loss of stereognostic perception may occasionally be due to a peripheral nerve lesion, but is more often the result of involvement of the parietal cortex, the optic thalamus or the posterior columns of the cord Lesions of the posterior columns which produce complete loss of position and vibratory sensation do not cause much, if any loss of touch This is a common finding, for example in the combined sclerosis of pernicious anemia The ability of a person to determine the exact location of a spot which is touched goes closely with the position sense and is lost in a lesion of the parietal cortex

The fibers for temperature and pain cross through the central part of the cord almost immediately and ascend on the opposite side in the spinothalamic tract They ultimately reach the thalamus and are redistributed for discrimination to the cortex Cortical lesions will rarely produce much disturbance of pain heat and cold sensations whereas a lesion of the thalamus does cause a severe diminution or loss of these forms of sensation Most of the fibers for light touch and deep pressure cross the cord immediately and ascend to the thalamus anterior to the spinothalamic tract The loss of sensation which one sees in a cortical lesion, that is involvement of the parietal lobe has more to do with the so-called gnostic sensation than the vital ones Thus pain, heat and cold are little affected if at all but stereognostic perception sense of position, spot localization the discrimination of the two points of a compass are involved *Vibratory sense* is not affected in cortical lesions *Dissociated sensory loss* occurs in syringomyelia where the lesion is usually in the central part of the cord A single lesion in this location will involve the fibers of pain, heat and cold which have entered by way of the posterior roots and are crossing The singling out of the functions of the posterior columns is seen in its most typical form in tabes and in the combined sclerosis of pernicious anemia, in which conditions position and vibration sensations are lost, while pain, heat, cold and touch are normal If pain sense is normal, heat and cold are likely to be so If position sense is normal, vibratory sense will likely be so, and if neither pain nor position senses are impaired, it will be unlikely that touch spot localization or stereognostic perception will be The ability of the individual to tell correctly numbers drawn on his skin by the examiner's finger, has been designated by Spiller as *graphesthesia* It goes with the gnostic sensibilities

It is always important to differentiate between hysteria and organic disease

Sensory loss in hysteria never corresponds to known anatomic distributions and is often bizarre and unusual The form of sensation most frequently lost in hysteria is pain This loss usually occurs after the patient has been examined by one or more physicians The part of the body which shows a loss of sensation will also often show loss of power or paralysis An extremity which presents a complete loss of power and sensation can have such findings if due to organic disease, only from a lesion of the peripheral nerves which go to that extremity If such were the case the extremity would show atrophy, loss of reflexes and reactions of degeneration findings which never occur in hysteria Paralysis of one side of the body if organic, may be accompanied by loss of all forms of sensation if the optic thalamus and internal capsule are involved but in such cases the deep reflexes will be increased ankle clonus and Babinski sign will be present and the abdominal reflexes lost on the side opposite the lesion Paralysis of one side of the body with loss of sensation due to hysteria will show no alteration of the reflexes neither deep nor superficial There often is deafness and blindness on the affected side and all forms of sensation are usually not equally involved

The deep reflexes are never lost in hysteria, but they may be hyperactive or exaggerated The superficial reflexes are normal and a pseudo ankle clonus may be present The pupillary reflex is not affected and the eye grounds are normal *Visual defects* in hysteria however are common especially the loss of panoramic vision or the occur

rence of the so called tubular vision Sudden loss of vision may occur in hysteria but may also be seen in certain toxic states such as nephritis in brain tumors and in multiple sclerosis The history of the illness will aid greatly in differentiating these forms of amaurosis Hysterical deafness may be detected by ear tests and also by the following reflex if a sudden noise is made beside a person whose hearing is normal the eyes blink If he is deaf from an organic cause no blinking would occur but if the deafness is due to hysteria the reflex arc being still intact the eyes will blink Casual conversation about an hysterically deaf person held in his presence may later on be repeated by him

Paralysis of a part of the body due to hysteria may simulate organic disease The reflexes are not altered the muscles are not atrophic the sensory loss is not according to anatomic distributions It must not be overlooked that hysteria may complicate an organic affection A patient who has had an organic paralysis may recover but an hysterical paralysis may ensue and prolong the illness Many cases of hysteria or functional nervous disorders are found in organic affections outside the nervous system especially in persons who are frightened by the physician and a bad prognosis given Atrophy of muscles fibrillary tremors reactions of degeneration pathologic reflexes fixed pupils, optic atrophy sensory loss according to known anatomic distributions and fever do not occur in hysteria

## Roentgenologic Studies

In recent years mechanical measures have been used extensively to aid in the diagnosis and the location of lesions especially tumors of the brain and spinal cord Dandy introduced the injection of air directly into the ventricles as a diagnostic procedure following this the practice of introducing air into the subarachnoid space by way of lumbar puncture was recommended these procedures are called ventriculography and pneumo-encephalography Whether ventriculography or encephalography should be done depends on the individual case If a brain tumor is undoubtedly present and cannot be accurately localized, ventriculography may be performed if a tumor is suspected encephalography may be cautiously performed The presence of papilledema and other signs of increased spinal fluid pressure are contraindications to encephalography An encephalogram should not be done in these cases in which a tumor of the posterior cranial fossa is suspected The procedure in doing an encephalogram is to remove 5 to 15 cc of fluid and to inject a corresponding amount of air This is repeated until from 100 to 150 cc of fluid have been removed and replaced with air Removal of such a large amount of fluid is a risky thing in brain tumors and should not be done routinely Both of these diagnostic measures are not without danger and death sometimes results from them Many of the patients are greatly shocked by either a ventriculogram or encephalogram

Angiography introduced by Moniz consists in the injection of a radiopaque substance (diodrast or thorotrast) into either the carotid or vertebral artery permitting *x* ray visualization of the cerebral vascular pathways It is useful in demonstrating aneurysms vascular malformations and sometimes tumors

To aid in the location of a spinal subarachnoid block such as is produced by a neoplasm pantopaque may be injected into the subarachnoid space either at the cistern magna or in the lumbar area As this substance is heavier than spinal fluid appropriate tilting of the patient on the fluoroscopic table will cause the oil to run up or down the spinal subarachnoid space

Any abnormalities present that impinge upon or block the column of radiopaque material may thus be seen fluoroscopically and films of course can be made as indicated Occasionally the oil may slip by a block and sometimes it is apparently arrested in its descent when no block exists It is wise to remove as much pantopaque as possible at the end of the procedure for if it is not removed it may remain in the spinal canal for years and rarely may produce signs of root irritation especially of the lower spinal roots In some cases a block in the spinal subarachnoid pathway may be vis

whereas the one with loss of vibratory sense feels nothing *Stereognosis* is the ability of an individual to recognize an object placed *in the hand*, by *appreciation* of its weight, size, shape or texture Loss of stereognostic perception may occasionally be due to a peripheral nerve lesion but is more often the result of involvement of the parietal cortex the optic thalamus *or the posterior* columns of the cord Lesions of the posterior columns which produce complete loss of position and vibratory sensation do not cause much, if any loss of touch This is a common finding, for example, in the combined sclerosis of pernicious anemia The ability of a person to determine the *exact location of a spot which is touched* goes closely with the position sense and is lost in a lesion of the parietal cortex

The fibers for temperature and pain cross through the central part of the cord almost immediately and ascend on the opposite side in the spinothalamic tract They ultimately reach the thalamus and are redistributed *for discrimination to the cortex* Cortical lesions will rarely produce much disturbance of pain, heat and cold sensations, whereas a lesion of the thalamus does cause a severe diminution or loss of these forms of sensation Most of the fibers for light touch and deep pressure cross the cord immediately and ascend to the thalamus anterior *to the spinothalamic tract* The loss of sensation which one sees in a cortical lesion, that is involvement of the parietal lobe has more to do with the so-called gnostic sensation than the vital ones Thus pain, heat and cold are little affected if at all but stereognostic perception sense of position, spot localization the discrimination of the two *points of a compass* are involved *Vibratory sense* is not affected in cortical lesions *Dissociated sensory loss* occurs in syringomyelia where the lesion is usually in the central part of the cord A single lesion in this location will involve the fibers of pain, heat and cold which have entered by way of the posterior roots and are crossing The singling out of the functions of the posterior columns is seen in its most typical form in tabes and in the combined sclerosis of pernicious *anemia*, in which conditions position and vibration sensations are lost, *while pain, heat*, cold and touch are normal If pain sense is normal, heat and cold are likely to be so If position sense is normal vibratory sense will likely be so, and if neither pain nor position senses are impaired, it will be unlikely that touch *spot* localization or stereognostic perception will be The ability of the individual to tell *correctly numbers drawn* on his skin by the examiner's finger, has been designated by Spiller as *graphesthesia* it goes with the gnostic sensibilities

It is always important to differentiate between hysteria and organic disease

Sensory loss in hysteria never corresponds to known anatomic distributions and is often bizarre and unusual The form of sensation most frequently lost in hysteria is pain This loss usually occurs after the patient has been examined by one or more physicians The part of the body which *shows* a loss of sensation will also often show loss of power or paralysis An extremity which presents a complete loss of power and sensation can *have such find* ings if due to organic disease, only from a lesion of the peripheral nerves which go to that extremity If such were the case the extremity would show atrophy, loss of reflexes and reactions of degeneration findings which never occur in hysteria Paralysis of one side of the body if organic *may be accompanied by loss of all forms of sensation* if the optic thalamus and internal capsule are involved, but in such cases the deep reflexes will be increased ankle clonus and Babinski sign will be present and the abdominal reflexes lost on the side opposite the lesion Paralysis of one side of the body with loss of sensation due to hysteria will *show no alteration* of the reflexes neither deep nor superficial There often is deafness and blindness on the affected side and all forms of sensation *are usually not equally* involved

The deep reflexes are never lost in hysteria but they may be hyperactive or exaggerated The superficial reflexes are normal and a pseudo ankle clonus may be present The pupillary reflex is not affected and the eye grounds are normal Visual defects in hysteria however are common especially the loss of panoramic vision or the occur

(albumin) per 100 cc and 50 to 80 mg of sugar per 100 cc Normally no organisms are present but on microscopic examination it may show an occasional lymphocyte

Tests which should be done on the spinal fluid include those for total protein, globulin cell count with differentiation quantitative sugar Wassermann and colloidal gold test If evidence points to the possibility of meningitis a smear of the spinal fluid should be made and the fluid should be cultured A yellowish fluid (xanthochromia) may be due to a hemorrhage which has occurred in the subarachnoid space some days before it also occurs in the Froin syndrome The fluid may be actually bloody, due to blood in the subarachnoid space caused for example by spontaneous subarachnoid bleeding traumatic subarachnoid bleeding or rupture of a cerebral hemorrhage into the ventricles with escape into the subarachnoid space It may also be due to faulty technic If lumbar puncture is performed daily bloody spinal fluid due to subarachnoid hemorrhage will gradually become less and less bloody and within a week or ten days will be clear but yellow In another week or ten days the fluid will become normal Extradural bleeding does not cause a discoloration of the spinal fluid

Cells if present should be counted and their type determined An increase in cells is present in any inflammatory condition in the subarachnoid space such as neurosyphilis and meningitis An increase in cells is called pleocytosis The cells are frequently increased in epidemic encephalitis and in acute anterior poliomyelitis where the cells are first of the polymorphonuclear variety and then become lymphocytic in a few days at the most Eosinophilia of the spinal fluid usually means parasitic involvement of the central nervous system In cases in which meningitis or encephalitis is suspected quantitative tests for sugar should always be done In meningitis or any type except syphilitic the amount of sugar in the spinal fluid is diminished or absent whereas in a virus involvement of the nervous system the amount of sugar is occasionally slightly increased It is increased in diabetes depending on the blood sugar The chlorides in the spinal fluid are reduced in the various forms of meningitis but especially in the tuberculous form where they usually fall below 640 mg per 100 cc

*Colloidal gold Test* —A curve high to the left with fives and fours predominating has been called the paretic curve It was thought to be diagnostic of general paresis, it may occur however in almost any form of neurosyphilis in meningitis and in multiple sclerosis If the curve is high in the middle it has been referred to as the tabetic or meningitic curve and is frequently seen in neurosyphilis and meningitis Such a curve may also be seen in multiple sclerosis and in other organic affections of the nervous system especially acute inflammatory disease

The spinal Wassermann is an extremely important part of the examination of the spinal fluid Quantitative tests may be most helpful in evaluating the progress of treatment or the recrudescence of the disease

The estimation of the amount of *protein in the spinal fluid* is important The normal content is 15 to 45 mg per 100 cc The amount of protein in the spinal fluid is increased in fluid obtained below a block and it may also be increased in cerebral neoplasms Most infectious diseases of the nervous system and many degenerative ones at least some time during their course will show varying degrees of increased protein

*Inoculation of guinea pigs* with fluid obtained from patients suspected of having tuberculous meningitis may be performed

The value of information obtained from a lumbar puncture cannot be overemphasized In view of the great frequency with which neurosyphilis is associated with a negative blood Wassermann it is imperative that every patient showing organic involvement of the nervous system have an examination of the spinal fluid The only exception to this rule should be those cases in which the possibility of a brain tumor exists and then it is permissible to perform a lumbar puncture in order to estimate the pressure If this is high no fluid should be withdrawn There are many cases of vascular disease and of inflammatory reaction of the brain that are confused with tumor and low spinal

utilized following the injection of air into the spinal canal (air myelography)

The necessity of these mechanical aids to diagnosis is inversely proportional to the physician's clinical skill

### ELECTRO-ENCEPHALOGRAPHY

Berger (1929–1934) demonstrated that the human cortex possessed an electrical beat or rhythm, originating in the neurons, and devised suitable technical methods for its recording (electrical encephalography) This electrical activity of the cortex has been found to vary with age sensory stimulation sleep, and various changes in the physico chemical state of the body The electro-encephalogram therefore is of some value in demonstrating the presence of disturbed cortical function

At present, the greatest clinical value of electro-encephalography is in the detection of the paroxysmal cerebral dysrhythmia which is present in a certain percentage of epileptic cases It is also of some value in the localization of focal brain lesions, particularly those lying close to the surface such as tumors While various electro-encephalographic changes have also been found in many other neurologic and psychiatric diseases *the changes are in no sense* specific and therefore are of little help in exact clinical diagnosis

*Electro-encephalography* in some cases is a helpful diagnostic adjuvant when the electro-encephalographic findings are interpreted *in* connection with the clinical history and examination, and other laboratory findings but it should not be considered as an infallible diagnostic method whose use makes careful clinical study superfluous

### CEREBROSPINAL FLUID

Spinal fluid is usually withdrawn for examination at the level of the $L_3$–$L_4$ vertebræ The amount of fluid neccessary for examination is from 8 to 10 cc

Before any fluid is withdrawn in spinal cord cases jugular compression should be done in order to determine whether or not a spinal subarachnoid block exists This is the *Queckenstedt test* In the normal individual when the jugular veins are compressed with the spinal manometer in place, the pressure in the *spinal manometer rises* promptly and, on the release of pressure on the jugulars, falls suddenly If, however, there is a block in the subarachnoid space above the puncture, the pressure rises little or not at all on jugular compression and falls slowly and in a step-ladder fashion The conditions which may cause a block are spinal tumors diseases and injuries of the vertebræ such as Pott's disease, extradural abscess, inflammatory conditions in the meninges especially acute purulent meningitis adhesions and serous meningitis Syringomyelia occasionally produces a block either partial or complete If a complete subarachnoid block exists two chambers for the spinal fluid are formed and the fluid below the block undergoes definite changes The protein content is increased, supposedly due to venous transudation The point of block may be determined by the injection of pantopaque into the cisterna magna with the patient sitting *The oil will fall to the* point of block and can be seen by means of the roentgen ray The oil may also be injected into the lumbar space and, with the patient in the Trendelenburg position, it stops at the lowest end of the block In *tumors of the cauda equina the protein* content is increased the fluid may be yellowish and coagulate readily In thrombosis of the lateral sinus the Ayer-Tobey modification of the Queckenstedt test may give valuable information Under such a condition, compression of the jugular vein on the side of the lesion does not cause a rise of the fluid in the manometer whereas compression on the normal side causes an elevation *The Queckenstedt test is of value only in determining whether or not a block exists in the spinal subarachnoid pathway* It is of no value in cases in which only an intracerebral lesion is suspected and in such cases it should not be performed because of the danger of compressing the cerebellar tonsils and medulla into the foramen magnum causing death

*Laboratory Examinations* —Normal spinal fluid is clear colorless alkaline it contains 700 to 750 mg of chlorides (as sodium chloride) per 100 cc 15 to 45 mg of protein

(albumin) per 100 cc and 50 to 80 mg of sugar per 100 cc Normally no organisms are present but on microscopic examination it may show an occasional lymphocyte

Tests which should be done on the spinal fluid include those for total protein globulin cell count with differentiation quantitative sugar Wassermann and colloidal gold test If evidence points to the possibility of meningitis a smear of the spinal fluid should be made and the fluid should be cultured A yellowish fluid (xanthochromia) may be due to a hemorrhage which has occurred in the subarachnoid space some days before it also occurs in the Froin syndrome The fluid may be actually bloody due to blood in the subarachnoid space caused for example by spontaneous subarachnoid bleeding traumatic subarachnoid bleeding or rupture of a cerebral hemorrhage into the ventricles with escape into the subarachnoid space It may also be due to faulty technic If lumbar puncture is performed daily bloody spinal fluid due to subarachnoid hemorrhage will gradually become less and less bloody and within a week or ten days will be clear but yellow In another week or ten days the fluid will become normal Extradural bleeding does not cause a discoloration of the spinal fluid

Cells if present should be counted and their type determined An increase in cells is present in any inflammatory condition in the subarachnoid space such as neurosyphilis and meningitis An increase in cells is called pleocytosis The cells are frequently increased in epidemic encephalitis and in acute anterior poliomyelitis where the cells are first of the polymorphonuclear variety and then become lymphocytic in a few days at the most Eosinophilia of the spinal fluid usually means parasitic involvement of the central nervous system In cases in which meningitis or encephalitis is suspected quantitative tests for sugar should always be done In meningitis of any type except syphilitic the amount of sugar in the spinal fluid is diminished or absent whereas in a virus involvement of the nervous system the amount of sugar is occasionally slightly increased It is increased in diabetes depending on the blood sugar The chlorides in the spinal fluid are reduced in the various forms of meningitis but especially in the tuberculous form where they usually fall below 640 mg per 100 cc

*Colloidal gold Test* —A curve high to the left with fives and fours predominating has been called the paretic curve It was thought to be diagnostic of general paresis it may occur however, in almost any form of neurosyphilis in meningitis and in multiple sclerosis If the curve is high in the middle it has been referred to as the tabetic or meningitic curve and is frequently seen in neurosyphilis and meningitis Such a curve may also be seen in multiple sclerosis and in other organic affections of the nervous system especially acute inflammatory disease

The spinal Wassermann is an extremely important part of the examination of the spinal fluid Quantitative tests may be most helpful in evaluating the progress of treatment or the recrudescence of the disease

ualized following the injection of air into the spinal canal (air myelography)

The necessity of these mechanical aids to diagnosis is inversely proportional to the physician's clinical skill

## Electro-encephalography

Berger (1929–1934) demonstrated that the human cortex possessed an electrical beat or rhythm, originating in the neurons, and devised suitable technical methods for its recording (electrical encephalography) This electrical activity of the cortex has been found to vary with age sensory stimulation, sleep and various changes in the physico-chemical state of the body The electro-encephalogram therefore is of some value in demonstrating the presence of disturbed cortical function

At present the greatest clinical value of electro-encephalography is in the detection of the paroxysmal cerebral dysrhythmia which is present in a certain percentage of epileptic cases It is also of some value in the localization of focal brain lesions, particularly *those lying close to the surface* such as tumors While various electro-encephalographic changes have also been found in many other neurologic and psychiatric diseases the changes are in no sense specific and therefore are of little help in exact clinical diagnosis

Electro encephalography in some cases is a helpful diagnostic adjuvant when the electro-encephalographic findings are interpreted in connection with the clinical history and examination, and other laboratory findings, but it should not be considered as an infallible diagnostic method whose use makes careful clinical study superfluous

## Cerebrospinal Fluid

Spinal fluid is usually withdrawn for examination at the level of the $L_3$–$L_4$ vertebræ The amount of fluid neccessary for examination is from 8 to 10 cc

Before any fluid is withdrawn in spinal cord cases, jugular compression should be done in order to determine whether or not a spinal subarachnoid block exists This is the *Queckenstedt test* In the normal individual when the jugular veins are compressed *with the spinal manometer* in place the pressure in the spinal manometer rises *promptly and, on the release of pressure* on the jugulars falls suddenly If however, there is a block *in the subarachnoid space* above the puncture the pressure rises little or not at all on *jugular compression, and* falls slowly and in a step-ladder fashion The conditions which may cause a block are spinal tumors, diseases and injuries of the vertebræ such as Pott's disease, extradural abscess, inflammatory conditions in the meninges, especially acute purulent *meningitis, adhesions and serous meningitis* Syringomyelia occasionally produces a block either partial or complete If a complete subarachnoid block exists, two chambers for the spinal fluid are formed and the fluid below the block undergoes definite changes The protein content is increased supposedly due to venous transudation The point of block may be determined by the injection of pantopaque into the cisterna magna with the patient sitting The oil will *fall* to the point of block and can be seen by means of *the roentgen ray* The *oil may also* be injected into the lumbar space and with *the patient in the Trendelenburg position* it stops at the lowest end of the block In tumors of the cauda equina the protein content is increased the fluid may be yellowish and coagulate readily In thrombosis of the lateral sinus the Ayer Tobey modification of the Queckenstedt test may give valuable information Under such a condition, compression of the jugular vein on the side of the lesion does not cause a rise of the fluid in the manometer whereas compression on the normal side causes an elevation *The Queckenstedt test is of value only in determining whether or not a block exists in the spinal subarachnoid pathway* It is of no *value in cases in which only* an intracerebral lesion is suspected and in such cases it should not be performed because of the danger of compressing the cerebellar tonsils and medulla into the foramen magnum causing death

*Laboratory Examinations* —Normal spinal fluid is clear colorless alkaline it contains 700 to 750 mg of chlorides (as sodium chloride) per 100 cc *15 to 45 mg of protein*

injury, which might impair the function of the roots In addition to Horner s syndrome which is present if the sympathetic rami are injured the small muscles of the hand and the flexors of the forearm are paralyzed Sensory disturbances are usually present and are limited to the ulnar side of the hand and forearm

### Erb Duchenne Paralysis

Upper brachial plexus palsy involving the fifth and sometimes the sixth cervical root is known as the Erb-Duchenne Paralysis It may occur as a birth injury as a result of a fall on the shoulder and occasionally following an anesthetic in patients in whom the arm has been abducted an externally rotated during the operation The paralyzed muscles include the biceps deltoid brachialis anticus supinator longus supra spinales infraspinatus rhomboids serratus magnus biceps latissimus dorsi and pectoralis major The arm hangs at the side and is internally rotated at the shoulder with the elbow extended and the forearm pronated Abduction and external rotation of the shoulders are lost the elbow cannot be flexed The biceps jerk is lost Movements of the wrist and fingers are unaffected Sometimes there is a small area of sensory loss over the deltoid In treatments the arm should be splinted with the shoulder abducted the elbow flexed and the forearm midway between pronation and supranation

### Landry s Paralysis

*Acute ascending paralysis* is a syndrome and not a disease Most instances of it are due to poliomyelitis disseminated encephalomyelitis and acute infectious polyneuronitis with cranial nerve symptoms The symptoms begin with flaccid paralysis of the feet and ascend rapidly and finally involve the bulb As a rule it produces death in three or four to ten days The paralysis is a flaccid one with loss of deep reflexes Sensation as a rule is not involved nor are the sphincters Atrophy is not seen because it does not have time to take place When the bulb is affected cranial nerve palsies may take place and death occurs from respiratory failure The treatment is supportive and the patient usually must be placed in a respirator

### Meniere s Syndrome

Due to an affection of the semicircular canals and the auditory nerve the three symptoms which make up this syndrome are deafness dizziness and tinnitus Nausea vomiting and sweating are secondary symptoms The condition may begin abruptly or may be a slowly progressive affair depending upon the etiologic factor Usually it occurs in the form of attacks An attack may come on suddenly with vertigo so severe that the patient drops as though struck Rarely he may be momentarily unconscious so that the diagnosis of epilepsy is considered Due to the intense dizziness he becomes nauseated vomits and breaks out in a cold perspiration and occasionally has diarrhea He is afraid to move because of dizziness which he fears may be increased by movement The acute attack may last from a few minutes to a few days The frequency of the attacks varies greatly

The pathology of the syndrome is obscure Toxemias intoxications syphilis malaria and occasionally tumor in the angle may produce the symptoms of Meniere s syndrome

The treatment must be directed to the cause Intracranial section of the vertibular branch of the eighth nerve has been suggested in those cases in which total deafness is present and intense vertigo still persists Bromide and luminal may cut down the frequency and severity of the attacks while investigation as to the cause is under way Some cases have been reported as being benefited by the intravenous injection of histamine (Horton) Talbott and Brown suggest the daily administration of 6 to 10 grams of potassium chloride given as a 25 per cent aqueous solution along with a diet low in sodium Nicotinic acid and thiamin hydrochloride may be helpful in some cases

## NEUROSYPHILIS

*Introduction* —Syphilis of the nervous system includes luetic diseases of the blood vessels of the brain and cord Syphilis rarely affects the peripheral nervous system The symptoms of neurosyphilis usually manifest themselves from five to fifteen years after the initial lesion However they may occur while the patient has the secondary rash or may be delayed thirty to forty-five years vascular neurosyphilis in particular may occur in the first years of the

pressure may be of great importance in helping to clear the diagnosis On the other hand it must be remembered that the spinal fluid pressure may be increased in some brain lesions of a non space taking nature as well as in patients who are tense during the procedure of lumbar puncture In patients obviously suffering from a brain tumor—a lumbar puncture is not needed for diagnostic purposes, but where the disks are normal and the symptoms and signs are nonconclusive it is advisable The great frequency of general paresis, and the many ways in which it may become manifest clinically makes it imperative that the spinal fluid be examined in every mental case and also in every patient suffering from what seems to be a psychoneurosis In arriving at the diagnosis of a patient in coma, an examination of the spinal fluid is as necessary and urgent as an investigation of the urine and blood

To avoid a headache following lumbar puncture, a narrow gauge needle should be used and the patient should be kept in bed with the head low for twenty four hours Fluids should be forced In some cases the incidence of postpuncture symptoms may be reduced by giving sodium amytal, gr 3 (0 2 gm ) prior to the procedure As little fluid should be removed as is necessary for the tests If the headache does occur it may last from a day to three or four weeks The headache is often accompanied by a pain in the neck, between the shoulders dizziness and even vomiting One cc of obstetrical pituitrin given hypodermically may relieve the distress or forty cc of sterile distilled water or 100 cc of a hypotonic sterile salt solution given intravenously may also be of benefit

## NEUROLOGIC SYNDROMES

Certain syndromes which will frequently be referred to under the name of the individuals who first described them are given below

### Brown-Sequard s Syndrome

This syndrome is due to a unilateral lesion of the cord It is caused by an injury such as those inflicted by stab or bullet wounds by disease, especially syphilis and by spinal tumors If one half of the cord at a distinct level is completely destroyed, the symptoms will be as follows paralysis of the spastic type with pyramidal tract and posterior column signs on the side of the lesion and below it, and anterior horn symptoms at the level of the lesion There may also be disturbance in all forms of sensation at the level of the lesion On the opposite side and below there will be loss of pain heat and cold and, in some cases, of touch and deep pressure In nontraumatic disorders it is rare to see a complete hemisection of the spinal cord

### Horner s Syndrome

This is a paralysis of the cervical sympathetic and results in the following symptoms enophthalmos which is due to paralysis of the non striated orbital muscle of Muller, miosis—the cervical sympathetic dilates the pupil and, if this function is paralyzed, the constrictor supplied through the third nerve functions unopposed and produces a small pupil The pupil does not dilate normally when shaded but contracts quickly to light and in convergence Narrowing of the palpebral fissure is due to paralysis of the non striated part of the levator palpebræ and also to the fact that, as the eyeball is retracted, the lids come closer together Vasomotor signs may also occur and the intraocular tension is diminished on the affected side Instillation of 2 per cent cocaine solution fails to dilate the pupil Furthermore stimulation of the side of the neck on which the paraly is exists does not produce dilatation of the pupil which it normally should do This is the ciliospinal reflex The disturbance of sweat secretion may be brought out by injection of pilocarpin Cervical sympathic paralysis may occur from lesions of the medulla such as syringobulbia and occlusion of the posterior inferior cerebellar artery by lesions within the cord and also by involvement of the eighth cervical or first thoracic root especially the latter and the ascending fibers of the cervical sympathetic in the neck The latter are frequently injured in operations of the neck

### Klumpke s Paralysis

A paralysis of the lower roots of the brachial plexus which is due to lesions which involve the nerves derived from the seventh and eighth cervical and the first dorsal roots The roots may be torn by a dislocated shoulder or efforts at reduction It may also be due to efforts at delivery especially breech births and also to any condition such as cervical rib, tumor syphilis or

injury, which might impair the function of the roots In addition to Horner s syndrome which is present if the sympathetic rami are injured the small muscles of the hand and the flexors of the forearm are paralyzed Sensory disturbances are usually present and are limited to the ulnar side of the hand and forearm

### Erb Duchenne Paralysis

Upper brachial plexus palsy involving the fifth and sometimes the sixth cervical root is known as the Erb-Duchenne Paralysis It may occur as a birth injury as a result of a fall on the shoulder and occasionally following an anesthetic in patients in whom the arm has been abducted an externally rotated during the operation The *paralyzed muscles include the biceps deltoid* brachialis anticus supinator longus supra spinales infra pinatus rhomboids serratus magnus biceps latissimus dorsi and pectoralis major The arm hangs at the side and is internally rotated at the shoulder with the elbow extended and the forearm pronated Abduction and external rotation of the shoulders are lost the elbow cannot be flexed The biceps jerk is lost Movements of the wrist and fingers are unaffected Sometimes there is a small area of sensory loss over the deltoid In treatments the arm should be splinted with the shoulder abducted the elbow flexed and the forearm midway between pronation and supranation

### Landry s Paralysis

*Acute ascending paralysis* is a syndrome and not a disease Most instances of it are due to poliomyelitis disseminated encephalomyelitis and acute infectious polyneuronitis with cranial nerve symptoms The symptoms begin with flaccid paralysis of the feet and ascend rapidly and finally involve the bulb As a rule it produces death in three or four to ten days The paralysis is a flaccid one with loss of deep reflexes Sensation as a rule i not involved nor are the sphincters Atrophy is not seen because it does not have time to take place When the bulb is affected cranial nerve palsies may take place and death occurs from respiratory failure The treatment is supportive and the patient usually must be placed in a respirator

### Meniere s Syndrome

Due to an affection of the semicircular canals and the auditory nerve the three symptoms which make up this syndrome are deafness dizziness and tinnitus Nausea vomiting and sweating are secondary symptoms The condition may begin abruptly or may be a slowly progressive affair depending upon the etiologic factor Usually it occurs in the form of attacks An attack may come on suddenly with vertigo so severe that the patient drops as though struck Rarely he may be momentarily unconscious so that the diagnosis of epilepsy is considered Due to the intense dizziness he becomes nauseated vomits and breaks out in a cold perspiration and occasionally has diarrhea He is afraid to move because of *dizziness which he fears may be increased* by movement The acute attack may last from a few minutes to a few days The frequency of the attacks varies greatly

The pathology of the syndrome is obscure Toxemias, intoxications syphilis malaria and occasionally tumor in the angle may produce the symptoms of Meniere s syndrome

The treatment must be directed to the cause Intracranial section of the vertibular branch of the eighth nerve has been suggested in those cases in which total deafness is present and intense vertigo still persists Bromide and luminal may cut down the frequency and severity of the attacks while investigation as to the cause is under way Some cases have been reported as being benefited by the intravenous injection of histamine (Horton) Talbott and Brown suggest the daily administration of 6 to 10 grams of potassium chloride given as a 25 per cent aqueous solution along with a diet low in sodium Nicotinic acid and thiamin hydrochloride may be helpful in some cases

## NEUROSYPHILIS

*Introduction* —Syphilis of the nervous system includes luetic diseases of the blood vessels of the brain and cord Syphilis rarely affects the peripheral nervous system The symptoms of neurosyphilis usually manifest themselves from five to fifteen years after the initial lesion However they may occur while the patient has the secondary rash or may be delayed thirty to forty five years vascular neurosyphilis in particular may occur in the first years of the

infection The effect of the spirochetal involvement of the nervous system is widespread, and while the location of the syphilitic process in a particularly vital spot may lead to disabling symptoms examination of other parts of the cord and brain in such a patient will reveal the fact that the disease has not been entirely localized One of the commonest manifestations of neurosyphilis is tabes dorsalis In this disease the pathology which accounts for the disabling symptoms in the lower extremities exists in the lumbo-sacral part of the cord, yet a considerable syphilitic process may and usually does, exist at the base of the brain in addition Why certain people with syphilis never develop disease of the nervous system is not known There is some evidence, but not entirely proved, that there may be a special neurotrophic strain of spirochetes with a predilection for the nervous system Conjugal neurosyphilis which is not infrequent, lends strength to the theory that a special strain of spirochetes exists Others believe that the occurrence of neurosyphilis depends upon the constitution of the individual Some believe that given a patient with syphilis, overwork, worry trauma and especially the excessive use of alcohol predispose to the occurrence of neurosyphilis It is certainly true that alcohol and syphilis do not mix well and the excessive use of the drug is a common point in the history of neurosyphilis It has been estimated that about 10 per cent of the patients in the hospitals for the mentally ill are there because of paresis or dementia caused by syphilis

*Types of Neurosyphilis* — Neurosyphilis is divided into the meningeal parenchymatous vascular and meningovascular types An isolated gumma or syphiloma is rare, although gummatous meningitis is common The syphilitic meningitis may occur at any part of the cerebrospinal axis but is particularly common in the region of the optic chiasm, in the interpeduncular space and in the cerebellopontine angle It also occurs in the spinal cord especially on the dorsal aspect The meninges are infiltrated with round and plasma cells The parts of the central nervous system beneath the involved meninges show evidence of inflammatory reaction in such cases the process may be referred to as meningoencephalitis and meningomyelitis Hypertrophic pachymeningitis usually found in the cervical cord consists of great thickening of the dura and is usually, but not always, due to syphilis This process leads to rim degeneration of the cord atrophy of the roots and involvement of the vessels which nourish the cord As a result, cavitation in the central parts of the cord often occurs

The two forms of neurosyphilis which are examples of the parenchymatous type are general paresis and tabes dorsalis Pathologically, general paresis is a syphilitic meningoencephalitis characterized by a fibrous thickening and infiltration of the meninges with round cells of the lymphocytic and plasma type In the cortex the findings are a breaking up of the cyto architecture independent of the vascular supply, perivascular infiltration with cells identical with those of the pia the occurrence of rod cells in great number and new vessel formation By means of special staining methods it is possible to detect the increase of iron and enormous numbers of so-called Hortega and Cajal cells of the glial type A certain percentage of cases probably not over 15, have sclerosis of the posterior columns of the cord and the usual syphilitic meningitis, producing the clinical picture that is commonly called taboparesis Remissions either spontaneous or as a result of therapeutic measures may bring about decided improvement in the pathologic picture Tabes is an affection of the posterior roots posterior ganglia and the meninges covering the dorsal aspect of the cord with secondary changes in the posterior columns Whether the lesion is primarily in the roots or the meninges has not been settled satisfactorily Very rarely in tabes the anterior roots and the anterior horn cells may be involved Basilar meningitis usually exists in tabes and accounts for the cranial nerve symptoms

In vascular syphilis the syphilitic process is found in the blood vessels more particularly in the arteries The muscular and elastic fibers are infiltrated with lymphocytes The walls of the vessels especially the intima are ultimately involved with the

formation of a thrombus in the vessels An artery may also be the site of an aneurysm although syphilis is not a common cause of aneurysm of the cerebral vessels If an artery is completely thrombosed or if it ruptures as the result of aneurysm cerebral softening or cerebral hemorrhage results

The relation of trauma to syphilis of the nervous system is an important one Trauma of course cannot produce neurosyphilis but it can bring out its symptoms or aggravate them The question of relationship between trauma and syphilis has a very direct medico legal significance

## GENERAL PARESIS

*Synonyms* —General paralysis of the insane dementia paralytica

*Introduction* —Among the various forms of mental disease there is none which may start in such a variety of ways and exhibit such a protean symptomatology as general paresis It has been known for a long time that the initial symptoms of paresis are often similar to those of the psychoneuroses the onset may also be with excitement depression or a paranoid trend Irritability, nervousness, bradyphrenia and other common neurophsychiatric complaints are among some of the frequent early symptoms

Paresis is a common mental disease making up about 10 per cent of those in mental hospitals and may masquerade under such different guises that it should always be thought of in any psychiatric disturbance occurring between the ages of twenty five and seventy years furthermore juvenile paresis is common enough in the psychoses of childhood

From a diagnostic standpoint too much stress has been laid upon the grandiose form of paresis and too little upon the other and more common ways in which the disease asserts itself Once general paresis is in full bloom with changes in character delusions of grandeur physical signs and mental deterioration a tyro can or at least should make the diagnosis with facility

*Symptoms* —All psychoneurotic manifestations should be considered as potentially due to paresis This is particularly so if these symptoms have come on in a male between the ages of twenty five and forty years without a history of previous attacks Mental symptoms which initiate syphilis may be those of excitement or depression the patient may simulate manic depressive insanity in either phase Ideas of grandeur especially in regard to strength and wealth are common but many diagnoses of paresis will be missed early if the physician waits for the appearance of ideas of grandeur Memory is impaired and judgment is affected in all lines This leads the paretic into difficulties especially in regard to alcohol and sex He becomes loose in his manner of dress and in his talk Because of lack of attention and loss of memory he loses interest in or ruins his business he forgets important appointments He often orders or buys an unwarranted amount of materials While the paretic is usually happy and euphoric he is also given to outbursts of temper and is frequently unmanageable While not usually suspicious the paretic may become extremely paranoid He rarely attempts suicide but may become assaultive especially if his aims are interfered with Some of the cases will pursue a course which runs into a state of simple dementia with mental dilapidation

In some cases mental symptoms are initially minimal or absent and the disease is ushered in by the occurrence of hemiplegia aphasia or convulsions These neurologic symptoms are often transient subsiding spontaneously within a few days

*Signs* —The physical signs of paresis are important and many of them are found in most cases The speech is of a tremulous slurred dysarthric variety and is made much worse if the patient drinks alcohol Test phrases such as Methodist Episcopal Hospital The Royal Riding Artillery Brigade and ' Peter Piper picked a peck of pickled peppers are said with difficulty The lips tongue and fingers show a distinct simple tremor The face has more or less of a masked expression The pupils are often of Argyll Robertson type but many cases of what might be considered early paresis will not show changes in the pupils and if possible the diagnosis should be made before they occur and before the presence of delusions of grandeur Ocular palsies and optic atrophy may be seen but are not as common

as they are in other forms of neurosyphilis All of the deep reflexes, because of cortical involvement, are increased but it is rare that ankle clonus or Babinski's sign appears The handwriting shows a tremor is carelessly done and letters words and even sentences may be left out when the patient writes from dictation If the posterior columns are affected Romberg's sign and a loss of the deep reflexes may be detected Paralytic attacks (hemiplegia monoplegia, aphasia) status epilepticus and partial continuous epilepsy may occur in the course of paresis The paralytic phenomena may disappear as quickly as they appeared Many of the patients become bedfast, emaciated develop infections in the urinary system have bed sores and finally die of pneumonia, tuberculosis or status epilepticus

*Laborlory Findings* —Examinations of the blood and spinal fluid are of great aid in the diagnosis of paresis In untreated patients practically 100 per cent will have a positive spinal fluid Wassermann The cell count may vary In a series of cases of ours it ranged from 1 to 400, the average being 31 Almost every untreated patient will show alteration in the colloidal-gold curve, such as 5555543321 fives and fours should predominate in the reading of the first 4 to 6 tubes The globulin is increased It must be remembered that cases of diffuse neurosyphilis non paretic in type can produce in the spinal fluid changes almost exactly similar to those of paresis The finding therefore, of a 4 plus Wassermann an increase in the cells and a colloidal gold curve of the paretic curve in the spinal fluid is not enough on which to base the diagnosis of ' general paresis The blood Wassermann is positive in 95 to 100 per cent of untreated patients If a case is supecteds to be one of general paresis has not received anti syphilitic treatment and the blood and spinal fluid are negative for syphilis, such an individual will usually be proved to have a brain tumor arteriosclerosis, chronic alcoholism, pernicious anemia or pellagra Multiple sclerosis frequently shows an alteration of the colloidal gold curve at some stage of the paretic type, but the Wassermann of the blood and the fluid are negative and there is no increase of cells

Before the advent of fever therapy the *prognosis* in paresis was very bad practically all cases dying within three years Since fever therapy, tryparsamide bismuth and penicillin have been used, more than 50 per cent of the cases do well and the span of life of the remaining is usually greatly increased

The *diagnosis* of paresis should be made as early as possible The frequency of the disease and the various ways in which it may begin make it imperative that every psychotic individual be examined physically and from the laboratory standpoint for syphilis Chronic alcoholism drug poisoning by such compounds as barbital frontal tumors pellagra, arteriosclerosis and multiple sclerosis may sometimes be mistaken for general paresis Occasionally the mental symptoms produced by pernicious anemia are similar to those of paresis It is in such instances that the laboratory is of great aid in ruling out the presence of syphilis Diffuse neurosyphilis especially that characterized by bilateral lesions either of softening or of gumma may produce a group of symptoms and laboratory findings that are almost indistinguishable from those of general paresis Hallucinations as a rule do not occur in paresis unless the patient is in addition an alcoholic Sometimes a patient with dementia precox, especially one of the paranoid type acquires syphilis and later develops neurosyphilis in such conditions hallucinations may be present

*Treatment* —The important considerations in the handling of a case of paresis are the protection of the patient the treatment of the underlying condition and if necessary the appointment of a guardian to handle his affairs and money The last used to be of great importance and remains so if the mental symptoms are severe The addition of penicillin to the treatment of paresis has however hastened the return of many paresis patients to normal productive lives Most paretics should be admitted to a mental hospital although many may be handled in a general one

The most important therapeutic procedures in the treatment of paresis are peni

cillin and fever therapy Some writers have expressed the opinion that penicillin alone is sufficient In our experience however fever therapy and penicillin together constitute the best treatment Every patient with general paresis if under 60 years of age and without serious medical complications *should receive fever therapy as soon as* possible Fever therapy was first used by Wagner von Juaregg who employed malaria as the source of the fever A diabetic may be carried through a course of fever with certain added precautions The same is true for a patient with tuberculosis Severe cardiacs react poorly to fever Nephritis is a contraindication to malaria or fever induced by killed typhoid organisms but a nephritic may be given fever cautiously in the Kettering hypertherm Patients with moderate or severe anemias should not be given malaria or typhoid vaccine but may receive fever in the hypertherm

Malaria in our opinion is the best state for fever therapy It is the most comfortable type of fever to endure no expensive machinery is required less nursing care is needed and it undoubtedly gives the best results The disadvantages are the incubation period involved which may vary in length from 5 days to 5 weeks or longer the indefiniteness of the time of the chill and following fever the lack of general availability of malaria and the progressive weight loss and the anemia that usually develop To state briefly 8 to 10 cc of blood taken preferably during a chill from a known case of malaria (tertian or quartan type) is given intravenously to the case under treatment (incompatibility of bloods may be overlooked) He should be allowed to have a total of 50 to 70 hours of fever over 103° (the temperature is orally taken) During the course of treatment the patient s physical condition should be checked daily and estimations of the hemoglobin and blood urea nitrogen should be made not less than twice weekly Termination of the malaria is indicated in the presence of rapidly increasing anemia a substantial increase in the blood urea nitrogen a high fever prolonged for more than 24 hours or signs of generalized collapse In some cases a rest period is all that is required to allow the patient to recuperate In such cases, thiobismal 0 1 to 0 2 grams given intramuscularly will usually stop the fever for 7 to 14 days If this drug is not effective or the malaria is to be completely terminated then quinine atabrine chlorguanide hydrochloride or chloroquin in appropriate dosage *is recommended* It should be *mentioned* here that penicillin may be given concurrently with malaria in the usual antisyphilitic doses it has no effect on the plasmodium Arsenicals and heavy metals should not be given during a course of malarial fever therapy

In patients unsuitable for malaria the Kettering hypertherm may be used Its advantages are that a few patients not medically suitable for malaria may be successfully carried through a course of fever One knows the time of the fever and how long it will last Patients especially negroes who will not take malaria may be given the hypertherm

A third type of fever is that induced by killed typhoid organisms Practically its only advantage in our opinion is that typhoid vaccine is usually available in all hospitals

To summarize it is our opinion that malaria is the best type of fever therapy for paretics the Kettering hypertherm is a good second and a most useful addition to a ward in which malaria is used Killed typhoid organisms should be used only if one of the other two are not available Patients should be well studied medically but the responsibility rests with the neurologist as to the choice of patients for fever The first responses from fever therapy may be noted after 10 to 20 hours and improvement usually continues rapidly for 3 to 6 months The full benefit may not be obtained for a year or more A second or third course of fever may be given as indicated

As mentioned above penicillin may be given at any time in relation to fever therapy It is our opinion that as soon as the diagnosis of paresis is established penicillin should be started A minimum of 10 million units should be given intramuscularly over a 10 to 15-day period Aqueous penicillin 100 000 units every 3 hours day and night for 100 injections (12½ days) crystacillin 300 000 units every 8 hours for 34 injections

a procaine penicillin in aluminum monostearate base, 900,000 units once daily for 12 days—these are suggested schedules.

Because of the mental symptoms, paretics are frequently subjected to electroconvulsive therapy. Generally speaking such treatment is to be condemned. We have recently read reports in which the authors advocated the use of electroshock as the sole treatment for paresis. The patients we have seen so treated may have been improved mentally for short periods of time, but all cases observed by us became very much worse within a few weeks and when the correct therapies were instituted did not do so well as might have been expected. Electroshock, however, does have a place in the management of paresis. Early in the course of fever and penicillin therapy it should be reserved for those episodes in which the patient becomes acutely excited, otherwise unmanageable or does not eat. Then and only if utterly necessary, a paretic should be given daily EST for 2 or 3 days. Later in the course of treatment, after fever has been completed and adequate penicillin has been given and the patient has not been making reasonable progress mentally, a series of electroshocks may be cautiously tried.

Unless the patient is markedly deteriorated on admission there will usually be sufficient improvement after fever and penicillin are completed for the patient to be discharged from the hospital. We believe that a paretic, or any patient suffering from luetic involvement of the central nervous system, should be followed for the rest of his natural life. Blood and spinal fluid tests on patients discharged after the above treatments are performed at monthly intervals for 3 months, then at quarterly intervals for the remainder of the first year. Thereafter such tests are done as indicated, usually at 4-, 6-, or 12-month intervals. Indications for out-patient treatment are inadequate treatment as an in-patient, not sufficient improvement clinically as an in-patient, progress of the disease or recurrence of signs and symptoms, marked increase in either blood or spinal-fluid titres. Drugs used in the further treatment of paresis have been tryparsamide, bismuth, mercury and iodides. The latter two are not used much at present and tryparsamide and bismuth may be supplanted by penicillin although tryparsamide is toxic to many paretics. Bismuth subsalicylate in oil may also be used. The injections are given intramuscularly, usually in the buttocks. The dose is 0.260 grams; a course of treatment, again, may last 16 weeks. Courses may be repeated after 2- to 4-week rest periods.

With the advent of the longer-acting depot penicillins we have done much experimental work with these drugs in the out-patient care of paresis. Though too early to give definite results, they do show great promise. At this writing we are using 5 cc. (1.5 million units) of a procaine penicillin in aluminum monostearate base weekly for 10 weeks as a single course of therapy. The only complication has been an occasional allergy which is usually controlled by antihistaminics. The place of aureomycin and other newer antibiotics has not yet been established in the therapy of paresis.

It sometimes becomes obvious that out-patient therapy is not adequate, that the patient is slipping and should be readmitted for further therapy (fever). In selected cases it has been possible to give fever therapy (Kettering hypertherm) on an out-patient basis.

In addition to fever, penicillin, *et al.*, it must be remembered to treat the individual as a human being, one who is sick with a chronic potentially devastating infection. Proper diet, rest, vitamins, freedom from fear and worry, the appointment of a guardian if deemed necessary and the absolute avoidance of alcohol are additional measures.

If an individual does not respond to adequate therapy, he should be resurveyed and the possibility of another disease, such as tumor, investigated.

## TABES DORSALIS

*Synonyms.*—Locomotor ataxia. Posterior spinal sclerosis.

*Symptoms.*—Tabes dorsalis is always due to syphilis, but there is a pseudotabes usually due to multiple neuritis with loss of deep sensation and caused by such conditions as diabetes and diphtheria, which may be mistaken for real tabes. As a rule five to

fifteen years elapse after syphilis has been acquired before the symptoms of tabes ensue However the writers have seen a case of tabes dorsalis bedridden because of ataxia fourteen months after the initial lesion Probably the commonest early symptom is pain which usually appears in the lower extremities in the buttocks and about the the abdomen The pain of tabes may occur in the chest in the upper extremities or in the distribution of the fifth nerve It has been described as a boring lancinating pain and patients have said that the pain feels as though it were produced by a knife stuck into the flesh and turned around It comes out of a clear sky and may last for a few moments hours or days If the symmetrical roots are involved the patient has a *girdle sensation* Occasionally pressure on the painful area will relieve the pain but not infrequently the area is as tender as though the patient had multiple neuritis The pains have a tendency to occur in spots the patient describes these spots as though they contained a thousand toothaches and could be covered with a dime or quarter The pain is mistaken for neuritis arthritis phlebitis acute abdominal conditions, pleurisy angina pectoris and hysteria

The next important group of symptoms are those referable to the functions of the conus Most common of these is the *disturbance in the control of the bladder* resulting in retention of urine incontinence and difficulty in passing it Any of these symptoms appearing in an adult for the first time hould arouse suspicion of syphilis of the nervous system Loss of control of the rectal sphincter is occasionally seen but more often constipation occurs Diminished or lost libido is also a symptom frequently complained of and is due to involvement of the lowest part of the cord Symptoms referable to *the cranial nerves* are next in importance Diplopia dimness of vision deafness bilateral facial palsy in fact any of the cranial nerves may be involved by the syphilitic meningitis which is so common at the base in cases of tabes dorsalis *Gastric crises* and other forms of crises are frequent and are seen in their worst form in the patients who have lancinating pains The usual form of crisis is a gastric one which like a lancinating pain may strike with lightning rapidity It is characterized by extreme pain in the abdomen and vomiting It may last for hours, or days and cause marked reduction in weight and severe dehydration of the patient The extremes of crises may vary from a mild affair to one which makes life unbearable The exact manner in which a crisis is produced is not known It is also needless to say that this is the type of patient who may be subjected to exploratory laparotomies Gastric and intestinal studies in these cases are normal Crises referable to the intestines rectum larynx and vision may be observed Paresthesias in the feet and especially along the ulnar borders of the hands and forearms may be early symptoms

Ataxia is not an early symptom It is due to changes in the posterior columns It is most noticeable to the patient when he walks in the dark or with his eyes closed *Trophic conditions* may be the first to be observed by the patient but as a rule are late in appearing The commonest trophic disorders are perforating ulcers found on the soles and Charcot joints which usually affect the hips knees and ankles The lumbosacral spine is not an infrequent site for Charcot joints

*Physical Signs* — When the patient is examined the following signs may be detected in the order of their importance and onset (1) loss of the deep reflexes especially the Achilles and the patellar The biceps and triceps are not involved early unless the patient has cervical tabes (2) pupillary abnormalities (3) cranial nerve signs including palsies deafness and optic atrophy (4) disturbance of pain sense in the areas in which the patient has pain this form of sensation is disturbed earliest in tabes much before vibration and position (5) ataxia of station and gait and ataxia in the upper extremities and (6) trophic disorders especially Charcot joints and perforating ulcers

The deep reflexes are lo t because of interruption of the reflex arc While the patellar reflexes are u ually the ones tested it is of equal importance to determine the Achilles reflexes as they may be the first to be lost The skin reflexes are not altered unless there

a procaine penicillin in aluminum monostearate base, 900 000 units once daily for 12 days—*these are suggested schedules*

Because of the mental symptoms paretics are frequently subjected to electroconvulsive therapy Generally speaking such treatment is to be condemned We have recently read reports in which the authors advocated the use of electroshock as the sole treatment for paresis The patients we have seen so treated may have been improved mentally for short periods of time but all cases observed by us became very much worse within a few weeks and when the correct therapies were instituted did not do so well as might have been expected Electroshock however, does have a place in the management of paresis Early in the course of fever and penicillin therapy, it should be reserved for those episodes in which the patient becomes acutely excited otherwise unmanageable or does not eat Then and only if utterly necessary a paretic should be given daily EST for 2 or 3 days Later in the course of treatment, after fever has been completed and adequate penicillin has been given and the patient has not been making reasonable progress mentally a series of electroshocks may be cautiously tried

## TABES DORSALIS

*Synonyms* —Locomotor ataxia Posterior spinal sclerosis

*Symptoms* — Tabes dorsalis is always due to syphilis but there is a pseudotabes usually due to multiple neuritis with loss of deep sensation and caused by such conditions as diabetes and diphtheria which may be mistaken for real tabes As a rule five to

fifteen years elapse after syphilis has been acquired before the symptoms of tabes ensue However the writers have seen a case of tabes dorsalis bedridden because of ataxia fourteen months after the initial lesion Probably the commonest early symptom is pain which usually appears in the lower extremities in the buttocks and about the the abdomen The pain of tabes may occur in the chest in the upper extremities or in the distribution of the fifth nerve It has been described as a boring lancinating pain and patients have said that the pain feels as though it were produced by a knife stuck into the flesh and turned around It comes out of a clear sky and may last for a few moments hours or days If the symmetrical roots are involved the patient has a *girdle sensation* Occasionally pressure on the painful area will relieve the pain but not infrequently the area is as tender as though the patient had multiple neuritis The pains have a tendency to occur in spots the patient describes these spots as though they contained a thousand toothaches and could be covered with a dime or quarter The pain is mistaken for neuritis arthritis phlebitis acute abdominal conditions pleurisy angina pectoris and hysteria

The next important group of symptoms are those referable to the functions of the conus Most common of these is the *disturbance in the control of the bladder* resulting in retention of urine incontinence and difficulty in passing it Any of these symptoms appearing in an adult for the first time should arouse suspicion of syphilis of the nervous system Loss of control of the rectal sphincter is occasionally seen but more often constipation occurs Diminished or lost libido is also a symptom frequently complained of and is due to involvement of the lowest part of the cord Symptoms referable to *the cranial nerves* are next in importance Diplopia dimness of vision deafness bilateral facial palsy in fact any of the cranial nerves may be involved by the syphilitic meningitis which is so common at the base in cases of tabes dorsalis *Gastric crises* and other forms of crises are frequent and are seen in their worst form in the patients who have lancinating pains The usual form of crisis is a gastric one which like a lancinating pain may strike with lightning rapidity It is characterized by extreme pain in the abdomen and vomiting It may last for hours, or days and cause marked reduction in weight and severe dehydration of the patient The extremes of crises may vary from a mild affair to one which makes life unbearable The exact manner in which a crisis is produced is not known It is also needless to say that this is the type of patient who may be subjected to exploratory laparotomies Gastric and intestinal studies in these cases are normal Crises referable to the intestines rectum larynx and vision may be observed Paresthesias in the feet and especially along the ulnar borders of the hands and forearms may be early symptoms

Ataxia is not an early symptom It is due to changes in the posterior columns It is most noticeable to the patient when he walks in the dark or with his eyes closed *Trophic conditions* may be the first to be observed by the patient but as a rule are late in appearing The commonest trophic disorders are perforating ulcers found on the soles and Charcot joints which usually affect the hips knees and ankles The lumbosacral spine is not an infrequent site for Charcot joints

*Physical Signs* —When the patient is examined the following signs may be detected in the order of their importance and onset (1) loss of the deep reflexes, especially the Achilles and the patellar The biceps and triceps are not involved early unless the patient has cervical tabes (2) pupillary abnormalities (3) cranial nerve signs including palsies deafness and optic atrophy (4) disturbance of pain sense in the areas in which the patient has pain this form of sensation is disturbed earliest in tabes much before vibration and position (5) ataxia of station and gait and ataxia in the upper extremities and (6) trophic disorders especially Charcot joints and perforating ulcers

The deep reflexes are lost because of interruption of the reflex arc While the patellar reflexes are usually the ones tested it is of equal importance to determine the Achilles reflexes as they may be the first to be lost The skin reflexes are not altered unless there

be a distinct loss of sensation in the distribution of the reflexes.

The same pupillary signs may occur in tabes as in other forms of syphilis. They may vary in size from pin point to wide dilatation, the inequality may be slight but the patient may have one pin point and one widely dilated pupil. The pupils are usually irregular, react sluggishly and, as the disease progresses, lose their reaction to light. The reaction to accommodation is preserved early (Argyll Robertson phenomena), but in an advanced case of tabes the pupils may be fixed. Occasionally the so called paradoxical reaction occurs in which the pupils dilate instead of reacting to light.

Any of the motor cranial nerves may be implicated but those which are commonly affected are the third and sixth. Bilateral seventh nerve palsy, especially if it is accompanied by bilateral eighth nerve symptoms, is usually due to syphilis. Optic atrophy in some degree is a frequent sign if it is looked for.

The common loss of sensation in tabes dorsalis is for pain. If the patient is seen early enough and tested for sensation it will usually be found that all forms of sensation are preserved except pain sense which is diminished, retarded or lost in the area in which the patient complains of pain or in a spotty distribution in the lower extremities. When ataxia becomes evident, position and vibration senses are disturbed.

Ataxia in station is called the *Romberg sign*. The patient standing with his feet together and with his eyes closed will sway abnormally if his sense of position is involved, and this is what finally happens in the tabetic. His gait is ataxic for the same reason; he throws the feet far, brings the heels down in a stamping manner; the feet are likely to be more widely separated than usual and the knees are hyperextended because of hypotonia and relaxation of the joints and tendons. Early ataxia in gait may be brought out by having the patient walk a "chalk line," by having him walk with his eyes closed or by walking backward. The patient himself complains that he walks poorly in the dark. The test for ataxia in the upper extremities is the finger to nose test and in this the patient with involvement of the cervical cord cannot accurately place his index finger on the tip of his nose with the eyes closed.

The joint most frequently the site of a Charcot joint (arthropathy) is the knee (*See Chapter 28*). Perforating ulcers usually occur on the soles of the feet. They are deep painless affairs and difficult to cure. Localized atrophy of the muscles occasionally occurs in tabes. A more common symptom is for the muscular system to become generally soft, flabby and underdeveloped. It is rare that one sees a fat tabetic.

Cystoscopic examination will reveal a 'cord' bladder.

*Laboratory Findings.*—The spinal fluid Wassermann is positive in 60 to 90 per cent of the untreated cases. The blood Wassermann is positive in approximately 50 per cent of the untreated cases. The cells of the spinal fluid are increased and may vary in number from 10 to 200 or 500 with an average of 30 to 75. The colloidal gold curve test shows an alteration to the left and in the middle such as 1223100000. Occasionally in tabes a stronger colloidal gold reaction may be found even of the paretic type.

The *diagnosis* of tabes should be made before marked physical signs present themselves. Pain, bladder disturbance and cranial nerve symptoms point directly to syphilis of the nervous system and most likely tabes. The diagnosis should be made before ataxia occurs. Tabes may be confused with the pseudotabetic form of multiple neuritis and with the combined sclerosis of pernicious anemia. The juvenile type of tabes due to congenital syphilis may be confused with Friedreich's ataxia or with a cerebellar tumor. Adie's syndrome may be confused with tabes dorsalis. It is a nonluetic condition characterized by tonic pupils and absent tendon reflexes. It usually occurs in young persons, especially females. One or both pupils may be affected. The typical tonic pupil has been previously described in the section on the third nerve. The pupillary disturbances may occur without reflex loss and conversely. The condition is benign and its cause is as yet undetermined. Negative serologic findings and the absence of the other signs and symptoms of tabes aid in its differentiation.

The course of tabes is usually slowly progressive but there are some cases which run a rapid course and the patients become bedfast or chairfast but then live on for years

*Treatment* —The patient should be placed in the best possible general health, his diet and mode of living made ideal alcohol tobacco and excesses of all sorts forbidden and plenty of sunshine, fresh air and rest prescribed He should not be permitted to take long walks to work until he is exhausted or to become overfatigued Massage and re-education of the ataxic extremities greatly benefits the tabetic Attacks of pain and crises may be relieved by analgesic drugs The signs once manifested rarely disappear under treatment For specific treatment *see* Chapter 3

### Other Forms of Neurosyphilis

In addition to paresis and tabes dorsalis syphilis may produce meningomyelitis myelitis Brown-Sequard s paralysis meningo-encephalitis bilateral cerebral lesions rarely gummas and endarteritis and hemiplegia due to vascular syphilis Occasionally syphilis of the spinal cord produces the so-called combined tabes which consists of the symptoms of tabes plus pyramidal tract signs Vascular syphilis affecting the nervous system comes on earlier than other forms of neurosyphilis In vascular neurosyphilis *the spinal fluid may be and often is*, negative The diagnosis of paresis should never be made in an untreated patient if the spinal fluid and blood are negative Treatment of these *other forms of neurosyphilis* usually consists of penicillin and fever therapy

## THE SPINAL CORD

### COMPRESSION OF THE SPINAL CORD

The cord may be compressed by disease of the vertebræ such as tuberculosis and malignancy, by fractures and dislocations of the spine by tumors either within or without the cord by abscesses by erosion of the vertebræ due to an aneurysm by inflammatory reactions by Hodgkin s disease and by leukemia In view of the fact that practically all of the conducting pathways between the brain and the parts below are in the spinal cord definite changes in motion and in the control of the sphincters result Segmental or radicular motor and sensory manifestations will often help in locating the site of the lesion

### TUMORS OF THE SPINAL CORD

Tumors of the cord may be intramedullary or extramedullary and the latter type may be either subdural or extradural Intramedullary tumors are usually gliomas The ordinary subdural tumor grows from the pia and the arachnoid the spinal root or the dura The extradural tumor grows between the vertebræ and the dura While all varieties of neoplasms occur in or about the spinal cord the commonest spinal cord tumors are endotheliomas and fibromas They are usually benign and encapsulated An extramedullary tumor, occurring intradurally is the usual finding The size of the tumor varies greatly The tumor frequently makes a nest for itself in the cord It displaces the cord and signs of compression are practically always seen

Tumors are more common in the dorsal and lower cervical cord than elsewhere The *symptoms* usually are slow in onset and as a rule sudden paralysis does not occur Unless the neoplasm is growing from the anterior and antero lateral surface which is not common the earliest symptom is pain Most tumors originate from the lateral or postero-lateral aspects of the cord and involve a *posterior root early in the history* The pain is usually unilateral and, as the tumor enlarges may be bilateral It follows a root zone and if it occurs about the trunk or abdomen *it may be interpreted as a* unilateral girdle sensation The pain is increased by sneezing jarring or coughing and is of a sharp stabbing nature Intramedullary tumors do not give rise to radicular pain but may produce central pain Occasionally tenderness to percussion and rigidity of the spine occur at the site of the tumor The symptoms and physical signs will vary greatly depending upon the location of the lesion The common type of tumor growing from the postero-lateral as-

be a distinct loss of sensation in the distribution of the reflexes

The same pupillary signs may occur in tabes as in other forms of syphilis They may vary in size from pin point to wide dilatation the inequality may be slight but the patient may have one pin-point and one widely dilated pupil The pupils are usually irregular, react sluggishly and, as the disease progresses lose their reaction to light The reaction to accommodation is preserved early (Argyll Robertson phenomena), but in an advanced case of tabes the pupils may be fixed Occasionally the so-called paradoxical reaction occurs, in which the pupils dilate instead of reacting to light

*Any of the motor cranial nerves may be implicated but those which are commonly affected are the third and sixth Bilateral seventh nerve palsy*, especially if it is accompanied by bilateral eighth nerve symptoms, is usually due to syphilis Optic atrophy in some degree is a frequent sign if it is looked for

The common loss of sensation in tabes dorsalis is for pain If the patient is seen early enough and tested for sensation it will usually be found that all forms of sensation are preserved except pain sense which is *diminished, retarded or lost in the area in which the patient complains of pain or in a spotty distribution in the lower extremities* When ataxia becomes evident, position and vibration senses are disturbed

Ataxia in station is called the *Romberg sign* The patient standing with his feet together and with his eyes closed will sway abnormally if his sense of position is involved and this is what finally happens in the tabetic His gait is ataxic for the same reason he throws the feet far brings the heels down in a stamping manner the feet are likely to be more widely separated than usual and the knees are hyperextended because of hypotonia and relaxation of the joints and tendons Early ataxia in gait may be brought out by having the patient walk a 'chalk line' by having him walk with his eyes closed or by walking backward The patient himself complains that he walks poorly in the dark The test for ataxia in the upper extremities is the finger to-nose test and in this the patient with involvement of the cervical cord cannot accurately *place his index finger on the tip of his nose* with the eyes closed

The joint most frequently the site of a Charcot joint (arthropathy) is the knee (*See* Chapter 28) Perforating ulcers usually occur on the soles of the feet They are deep painless affairs and difficult to cure Localized atrophy of the muscles occasionally occurs in tabes A more common symptom is for the muscular system to become *generally soft flabby and underdeveloped It is rare that one sees a fat tabetic*

Cystoscopic examination will reveal a *cord bladder*

*Laboratory Findings* — The spinal fluid *Wassermann is positive in 60 to 90 per cent* of the untreated cases The blood Wassermann is positive in approximately 50 per cent of the untreated cases The cells of the spinal fluid are increased and may vary in number from 10 to 200 or 300 with an average of 30 to 75 The colloidal gold curve test shows an alteration to the left and in the middle such as 1223100000 Occasionally in tabes a stronger colloidal gold reaction may be found even of the paretic type

The *diagnosis* of tabes should be made before marked physical signs present themselves Pain bladder disturbance and cranial nerve symptoms point directly to *syphilis of the nervous system* and most likely tabes The diagnosis should be made *before ataxia occurs* Tabes may be confused with the pseudotabetic form of *multiple neuritis and with the combined sclerosis of pernicious anemia* The juvenile *type of tabes due to congenital syphilis* may be confused with Friedreich s ataxia or with a cerebellar tumor Adies syndrome may be confused with tabes dorsalis It is a nonluetic condition characterized by *tonic pupils* and absent tendon reflexes It usually occurs in young persons *especially females* One or both pupils may be affected The typical tonic pupil has been previously described in the section on the third nerve The pupillary disturbances may occur without reflex loss and conversely The condition is benign and its cause is as yet undetermined Negative serologic findings and the absence of the other signs and symptoms of tabes aid in its differentiation

osteosarcoma may arise in the vertebral column from a neighborhood primary growth

The tumor usually involves two or more vertebræ In fact, in carcinoma all of the vertebræ may be diseased The roots are infiltrated as they pass to and from the cord The meninges are involved An important point to appreciate is that after a primary growth has been successfully removed metastasis to the spine may occur Acute angulation of the spine does not as a rule, occur and the exquisite tenderness seen in cases of Pott s disease is not common Pain is the most frequent and most distressing feature of this disease At first it is of a root nature the location of which depends upon the vertebra first affected As the disease progresses the patient develops usually suddenly symptoms of spinal cord compression The roentgenogram will aid greatly in the diagnosis but it is true here, as in Pott's disease that roentgen ray pictures made of the spine early in the disease may fail to show metastasis

Myeloma leukemia and Hodgkin's disease may involve the spinal cord directly or through metastasis to the vertebræ

*Treatment* of malignancy of the vertebræ is ineffectual The patient should be kept under the influence of narcotics or a cordotomy or lobotomy should be done Deep roentgen ray therapy or radium may be tried but are usually of no value except to relieve pain Testosterone and estrogens have been used for the relief of pain (*See* Chapter 28 )

## EPIDURAL AND SUBDURAL ABSCESS OF THE SPINAL CORD

Occasionally in the course of abscess formation anywhere in the body but more frequently secondary to boils on the back or on the neck a collection of pus or inflammatory material may localize in the epidural or more rarely in the sub dural space This usually occurs in the mid dorsal region The most constant early symptom is severe backache followed by root pains and then more or less slowly progressing pressure on the spinal cord with signs of block Fever leu kocytosis and other signs of infection are usually present There may be localized tenderness over the spine If the nature of the illness is recog nized operation should be done immediately with a fair chance of success

## CIRCUMSCRIBED SEROUS SPINAL MENINGITIS

This condition, which is usually confused with spinal cord tumor, is a circumscribed collection of fluid in the meninges The symptoms are indefinite and are usually those due to com pression of the cord which if long continued may lead to secondary degeneration It may come on as the result of meningitis but often the etiology is obscure Trauma may be a contributing factor Backache root pain weakness in the lower extremities and symptoms of a mild compression usually complete the picture The treatment is surgical evacuation of the fluid

## TUBERCULOUS SPONDYLITIS (CARIES OF THE SPINE POTT S DISEASE)

Tuberculosis of the spine usually begins in the bodies of the vertebræ occasionally in the joints or the ligaments and very rarely in the arches and processes The disease progresses rather slowly to caseation and necrosis The cord is not usually involved by deformity of the vertebræ or by the bone disease but by an extradural collection of the tuberculous pus The dura becomes greatly thickened but is rarely ruptured It is also unusual for a tuberculoma to be seen in the spinal cord of a patient suffering from Pott s disease As the vertebræ become more diseased a knuckling occurs at the site of the lesion The abscess which results from the tuberculous caries may point in the retropharyngeal space in the region of the psoas muscle or posteriorly While tuber culous caries may be primary it is practically always secondary to tuberculosis elsewhere in the body It occurs most frequently in the dorsal region and while most common in children it is frequently seen in adults At the site of compression the cord may be swollen but is usually compressed In a case of long standing secondary degeneration occurs in the cord

The first *symptom* is localized pain in the diseased vertebra Pain which is usually of a dull type is increased by any movement but especially by jarring sneezing or cough ing Early in the course of the disease the spine is held rigid by reflex action Tenderness on percussion will be found or, if the head is sharply depressed pain will

pect of the cord will produce pain of a radicular type, followed by hyperesthesia or loss of sensation in the distribution of the root or roots which are affected. If the tumor is far enough anterior to involve the anterior horns, signs of *compression of these structures* will be noted at the level of the tumor. As the tumor presses against the cord a Brown-Sequard paralysis which may not be entirely complete occurs. Bilateral pyramidal tract symptoms may be seen, and later on signs of interruption of all the pathways in the spinal cord may come on. If the tumor lies directly over the posterior columns, the *functions of the posterior columns and of the pyramidal tracts are severely interfered with.* If the tumor lies on the anterior aspect of the cord a syringomyelic loss of sensation may occur below the level of the tumor. Difficulty in the control of the sphincters appears as the spinal cord compression progresses. Reflexes of defense are seen in cases that have severe or complete paralysis. Signs of a subarachnoid block, most important in the diagnosis of a spinal cord tumor are present. *The cells in the spinal fluid are* not usually increased. The colloidal gold curve may show alterations. The roentgenogram, pantopaque and air myelography may be used as an aid in localization.

*Intramedullary tumors* are usually without pain except, and that rarely, of a burning type. *The symptoms are likely to be bilateral* and symmetrical and very often of a syringomyelic type. Before any suspected spinal cord tumor is operated upon, malignancy throughout the body should be ruled out, careful roentgen ray studies made of the spine, search made for syphilis both by clinical and laboratory *examinations and* the possibility of localized subdural infections ruled out.

The differential *diagnosis* is to be made from diseases of the vertebrae, various conditions which produce degeneration in the spinal cord such as syphilis, multiple sclerosis, the combined sclerosis of anemia, pachymeningitis and subdural abscess.

The correct *localization* is the *sine qua non* for surgical success. A tumor involving the *cauda equina* will bring about signs and symptoms according to the roots affected. Pain is a common and distressing symptom. Paralysis when it occurs is of the flaccid type. Loss of control of the sphincters and impotence takes place. Pain and other forms of sensation are lost. *Tumors of the conus* (the four lowest segments of the cord, i.e., S, 3, 4, 5 and coccygeal, 1) resemble symptomatically those of the cauda, with *the following exceptions*: (1) *lesions of the conus usually produce symmetrical, of the cauda, non-symmetrical symptoms and signs*; (2) saddle anesthesia is more common in lesions of the conus; (3) sphincter involvement and loss of potency occur more often in lesions of the conus; (4) fibrillations occur in conus disease; (5) dissociated loss of sensation is seen in conus involvement, *and (6) paralysis of the lower extremities and alteration of the patellar reflexes do not* happen as long as the lesion is confined to the conus; those signs are common in lesions of the cauda equina.

*Cervical cord tumors* often produce rigidity of the neck, spinal hemiplegia and ultimately tetraplegia. With a cervical tumor severe pain, atrophy, loss of the deep reflexes, *Horner's syndrome or Klumpke's syndrome* may be found.

Localization of the tumor will be made upon (1) the area in which the early pain of root irritation occurred, (2) the sensory level and whether it is segmental or root, (3) the extent of the motor paralysis, (4) the *presence of localized atrophy*, (5) reflex alterations or inequality.

Careful repeated sensory examination with comparison of the results with sensory charts will help most in the localization.

The *treatment* is surgical.

## TUMORS OF THE SPINE

Any form of malignancy including myeloma may involve the vertebral column but carcinoma and sarcoma are the most common. Carcinoma of the spine is always metastatic in origin. *It most frequently arises from a primary lesion in the lung*, prostate, rectum or breast, although carcinoma anywhere in the body may metastasize to the spine. It may occur at any time in the history of carcinoma and in a number of cases *the primary growth had not been* discovered before death. Sarcoma and

occur at the diseased vertebræ Spinal deformity in the nature of a kyphosis may occur at any time in the disease although, unless the vertebræ collapse kyphosis is a late symptom When the roots are affected sharp, shooting radicular pains of a type seen in any condition affecting a posterior root occur These pains may be unilateral or bilateral and, if sensation is tested in these painful areas, some loss of sensation will be found especially for pain The site of the radicular pains will naturally depend upon the level of the lesion The girdle sensation may occur at the site of the lesion Involvement of the anterior roots will cause atrophy flaccid palsy and a loss of the deep reflexes in their distribution As the cord is pressed upon by the cold abscess signs of a spastic paralysis occur below the level of the lesion Sensory symptoms also come on and if the disease is unchecked all forms of sensation and of motion are lost below the lesion Due to the involvement of the antero lateral tracts a loss of pain heat and cold may be the first sensory lack Sphincter disturbance trophic and vasomotor signs bed sores and urinary infections are seen The onset is usually slow taking weeks or months to develop but occasionally if the vertebra suddenly gives way or if the blood supply is interfered with by compression the signs may be acute in their manifestation If the lumbo-sacral region is the site of caries a flaccid palsy occurs in the lower extremities with excruciating pain If the cervical spine is involved flaccid paralysis in the upper extremities and a spastic paralysis below may be noted If a high cervical Pott's disease is present all four extremities may be very weak and spastic and respiratory disturbances and bulbar symptoms may also be manifested as the upper vertebræ are diseased Reflexes of defense and involuntary jerkings of the lower extremities are common physical signs when the cord is markedly compressed These signs practically always indicate severe involvement Fever is present or absent depending on the presence of complications or of tuberculosis elsewhere in the body About one-half of the patients die Those with involvement of the dorsal vertebræ have the best chance of a good outcome While the paralysis may clear up some people suffer permanent loss of power even though the tuberculous process heals The hunchback usually represents a healed Pott's disease

The spinal fluid is frequently xanthochromic and may coagulate spontaneously Signs of a subarachnoid block are usually present Roentgenograms will usually be characteristic but are often negative for evidence of the disease in its early stages It is imperative, therefore not to permit one negative roentgenogram to keep one permanently away from the diagnosis of Pott's disease Malignancy of the spine tumors of the cord, spondylitis spinal syphilis aneurysm and hysteria are to be considered in the diagnosis If every patient showing paralysis of spinal origin were subjected to careful roentgen ray studies of the spine spinal puncture for evidence of syphilis and block and careful repeated neurologic examinations only a rare case would be diagnostic problem

The *treatment* of this condition is primarily that of tuberculosis Orthopedic operations are sometimes indicated and some brilliant results come from them Extension and immobilization of the spine are necessary Streptomycin and other antibiotics should be given An air bed or water bed careful nursing, especially for the prevention of bed sores are important The evacuation of an abscess is indicated if present Even after paralysis has lasted some months complete recovery may occur

## INJURIES TO THE SPINAL CORD

The spinal cord may be injured by fracture dislocation fracture dislocation stab wounds bullet wounds concussion or by hemorrhage into the cord as a result of trauma the vertebræ escaping damage

As in skull fracture and cerebral implication injury is of importance in direct relation to the amount of cord damage done The cord may be completely severed or merely concussed Hemorrhage may occur into the substance of the cord The symptoms which come on as a result of fracture or fracture-dislocation gunshot wounds and stab wounds will vary with the location of the injury If the lesion is high bulbar

symptoms may be seen Root pains and the signs of a spinal cord compression which may vary from slight involvement to complete loss of all functions below the level of the injury may be seen Occasionally a Brown-Sequard syndrome may make up the picture Reflexes of defense may be detected If the cord is completely destroyed at a certain level a flaccid palsy with loss of all reflexes below may be seen (Bastian s law) If a patient with a complete lesion of the cord does not die from shock or injury within the first week or two, the lower end of the cord regains a certain amount of automatic function, including that of the bladder The reflexes may become extremely active below the lesion and the slightest stimulation below it may produce a series of mass reflexes, occasionally with evacuation of the bladder

## HERNIATION OR PROTRUSION OF INTERVERTEBRAL DISKS

Herniation or protrusion of an intervertebral disk has come to be recognized as a not uncommon cause of nerve root or spinal cord compression

*Etiology* —Since the majority of protruded disks are found in those regions of the spine where the vertebral column is subject to the greatest mechanical stress on heavy lifting or pushing it is thought that in most cases the protrusion results from trauma In many cases however no definite history of injury can be elicited It is possible that repeated strain or mild trauma incidental to the wear and tear of daily activity may result in degenerative changes in the disk, and that this is a contributing etiologic factor

*Pathology* —The most common site of the protrusion is found in the lower lumbar spine In over 90 per cent of cases the site of the lesion is at the third fourth or fifth lumbar vertebræ but protrusions also occur in the lower cervical and mid and low thoracic area The protrusion may be of a single disk or multiple Frequently there is an associated hypertrophy of the ligamentum flavum which extends between the laminæ and in some cases hypertrophy of this ligament alone is found to be the cause of symptoms

*Symptoms* —The condition is more common in men than in women The symptomatology varies somewhat depending on the region involved, but the most common complaint is back or neck pain, almost always intermittent in character, which is aggravated by coughing sneezing, or straining In some cases, a history may be obtained of the onset of the pain immediately following heavy lifting or straining This pain may later spontaneously subside only to recur some time later following subsequent trauma often of a mild character

In the cervical and thoracic regions, the symptoms and signs are more or less characteristic of an extramedullary cord tumor except that the pain is more likely to be intermittent In lateral herniations in the cervical area the pain often of a root character is referred to the neck or the upper extremity and weakness, sensory and reflex changes may be found in one arm or the other If the herniation however occurs in the midline symptoms referable to the neck and upper extremity may be minimal The outstanding symptoms are usually spasticity of the lower extremities and disturbances in gait Signs of pyramidal tract involvement are present but sensory signs and sphincter disturbances are minimal Such cases may simulate multiple sclerosis When the lumbar region is involved the patient complains of intermittent low back pain with or without radiation down the posterior aspect of one or both legs (sciatic nerve distribution) Frequently there is an accompanying spasm of the lumbar back muscles and a loss of the normal lumbar lordosis Tenderness may be present over the course of the sciatic nerve and Laseque s sign is usually positive The ankle jerk may be diminished or absent and much more rarely the knee jerk Radicular zones of hypesthesia and hypalgesia are found in about one third of the cases Muscular weakness may be present Sphincter disturbances are uncommon

Lumbar puncture may show the presence of some degree of block on jugular compression in about one half of the cases in which the herniation occurs in the cervical or thoracic region but when lumbar region is involved a block is seldom present and

occur at the diseased vertebræ. Spinal deformity in the nature of a kyphosis may occur at any time in the disease although unless the vertebræ collapse, kyphosis is a late symptom. When the roots are affected sharp shooting radicular pains of a type seen in any condition affecting a posterior root occur. These pains may be unilateral or bilateral and, if sensation is tested in these painful areas some loss of sensation will be found especially for pain. The site of the radicular pains will naturally depend upon the level of the lesion. The girdle sensation may occur at the site of the lesion. Involvement of the anterior roots will cause atrophy flaccid palsy and a loss of the deep reflexes in their distribution. As the cord is pressed upon by the cold abscess signs of a spastic paralysis occur below the level of the lesion. Sensory symptoms also come on and if the disease is unchecked all forms of sensation and of motion are lost below the lesion. Due to the involvement of the antero-lateral tracts a loss of pain heat and cold may be the first sensory lack. Sphincter disturbance trophic and vasomotor signs bed sores and urinary infections are seen. The onset is usually slow, taking weeks or months to develop but occasionally if the vertebra suddenly gives way or if the blood supply is interfered with by compression the signs may be acute in their manifestation. If the lumbo-sacral region is the site of caries a flaccid palsy occurs in the lower extremities with excruciating pain. If the cervical spine is involved flaccid paralysis in the upper extremities and a spastic paralysis below may be noted. If a high cervical Pott s disease is present, all four extremities may be very weak and spastic and respiratory disturbances and bulbar symptoms may also be manifested as the upper vertebræ are diseased. Reflexes of defense and involuntary jerkings of the lower extremities are common physical signs when the cord is markedly compressed. These signs practically always indicate severe involvement. Fever is present or absent depending on the presence of complications or of tuberculosis elsewhere in the body. About one-half of the patients die. Those with involvement of the dorsal vertebræ have the best chance of a good outcome. While the paralysis may clear up some people suffer permanent loss of power even though the tuberculous process heals. The hunchback usually represents a healed Pott s disease.

The spinal fluid is frequently xanthochromic and may coagulate spontaneously. Signs of a subarachnoid block are usually present. Roentgenograms will usually be characteristic but are often negative for evidence of the disease in its early stages. It is imperative therefore not to permit one negative roentgenogram to keep one permanently away from the diagnosis of Pott s disease. Malignancy of the spine tumors of the cord spondylitis spinal syphilis aneurysm and hysteria are to be considered in the diagnosis. If every patient showing paralysis of spinal origin were subjected to careful roentgen ray studies of the spine spinal puncture for evidence of syphilis and block and careful repeated neurologic examinations only a rare case would be diagnostic problem.

The *treatment* of this condition is primarily that of tuberculosis. Orthopedic operations are sometimes indicated and some brilliant results come from them. Extension and immobilization of the spine are necessary. Streptomycin and other antibiotics should be given. An air bed or water bed careful nursing especially for the prevention of bed sores are important. The evacuation of an abscess is indicated if present. Even after paralysis has lasted some months complete recovery may occur.

## INJURIES TO THE SPINAL CORD

The spinal cord may be injured by fracture dislocation fracture dislocation stab wounds bullet wounds concussion or by hemorrhage into the cord as a result of trauma the vertebræ escaping damage.

As in skull fracture and cerebral implication injury is of importance in direct relation to the amount of cord damage done. The cord may be completely severed or merely concussed. Hemorrhage may occur into the substance of the cord. The symptoms which come on as a result of fracture or fracture-dislocation gunshot wounds and stab wounds will vary with the location of the injury. If the lesion is high bulbar

The pyramidal tracts the anterior horn cells of the cord and sometimes the nuclei of the seventh, ninth, tenth and twelfth cranial nerves are affected The usual case begins with involvement of the anterior horn cells and the pyramidal tracts in the lower cervical and upper dorsal cord The cause of the disease is unknown Occasionally a patient who has had acute anterior poliomyelitis may later develop amyotrophic lateral sclerosis It is of interest that many sufferers with this disease give a history of having been unusually active in athletics or in occupations involving heavy use of the muscles for many years Trauma as a cause has to be considered but there is no definite evidence on which to base it A few cases have been reported in which the disorder developed in the upper extremities of workers using compressed air drills

*Symptoms* — The age of onset is usually between thirty and fifty years although the disease may occasionally be seen in childhood

The motor fibers are involved in the pons peduncles and occasionally even the cells of the motor cortex are affected The signs of the anterior horn disease are usually the first symptoms to occur and these are exhibited in the hands with a gradual progression upward so that the forearms arms shoulder girdles and neck muscles may become atrophic At the same time or shortly afterward pyramidal tract signs appear in the lower extremities the reflexes may also be increased in the upper extremities as long as there are cells remaining in the anterior horns to transmit the reflexes Claw hand results and the patient may ultimately be paralyzed in all four extremities When the cranial nerve nuclei are affected by the disease the signs of bulbar palsy ensue Pain is uncommon but a tired sensation may be noted in the muscles undergoing or about to undergo atrophy

The *prognosis* is poor most cases succumbing within three years although a few cases survive for longer periods The onset of a bulbar palsy always hastens the end which may be due in such cases to choking secondary to the lodging of a piece of food in the trachea or to an aspiration pneumonia

The *differential diagnosis* is to be made from spinal syphilis which may simulate very closely amyotrophic sclerosis progressive spinal muscular atrophy atrophy produced by arthritis syringomyelia and cervical Pott's disease

The *treatment* is usually ineffectual Wechsler reported improvement in some cases following the administration of vitamin E (alpha tocopherol) (ephynal) but this has not been confirmed Careful nursing selection of food which can be easily swallowed and the avoidance of overexertion are important

## PROGRESSIVE SPINAL MUSCULAR ATROPHY

This disease is rare only 10 cases having been seen at the Philadelphia General Hospital in a ten year period No verified cases were found in *a series of over 6000 neurologic autopsies* It begins in middle life although there is a familial form which may be seen in infancy or childhood The anterior horn cells of the spinal cord are involved and just as in amyotrophic lateral sclerosis the nuclei of the seventh ninth and twelfth cranial nerves may be affected The process which begins insidiously is slowly progressive affects the lower cervical and upper dorsal cord first from which it spreads both upward and downward

The *symptoms* are those of anterior horn disease Whereas amyotrophic sclerosis usually kills in less than three years sufferers from progressive spinal muscular atrophy may live five to twenty years

The *treatment* is essentially that of amyotrophic lateral sclerosis

## COMBINED SCLEROSIS DUE TO PERNICIOUS ANEMIA (POSTEROLATERAL SCLEROSIS)

The cord changes which occur in primary anemia commence in the posterior columns and in the pyramidal tracts both are involved at approximately the same time although disease of either one may slightly antedate the other Severe secondary anemia and occasionally cachexia from any cause may produce a similar picture Posterolateral sclerosis may also occur without any evidence of disturbance of the hematopoietic functions While the exact cause of the degeneration of the spinal cord is not known it is likely that the same *etiologic factor*

the only abnormality found may be an increase of the spinal fluid protein

*Diagnosis* —The diagnosis may frequently be established on clinical evidence alone (when the lumbar area is involved) on the basis of a history of intermittent low back pain aggravated by coughing straining or sneezing with pain radiating down one or both legs, but myelography is usually necessary particulary in cases of cervical herniation

*Treatment* —When the herniation is in the lumbar area conservative treatment including complete bed rest physiotherapy and administration of salicylates, will often give relief It should be tried for at least a month If the pain still persists or the patient has occurrent attacks surgical intervention is indicated While some cases are therby completely relieved of pain we have seen many patients in whom a protruded disk was found and removed at operation but who continued to have pain Surgery in cases with cervical herniation is dangerous but a decompressive laminectomy is often helpful

## HEMATOMYELIA

*Hemorrhage into the spinal cord* is practically always the result of trauma It usually involves the gray matter and most often that about the central canal It is important to appreciate that hematomyelia may occur without injury to the vertebræ One or more segments may be involved by the hemorrhage the location of which depends upon the site of the injury although the cervical and lumbosacral regions seem most susceptible to trauma While the trauma which causes it is usually direct cervical hematomyelia may follow a blow on the head Hematomyelia may also be caused by a fall on the buttocks or by landing on the feet after a fall of considerable distance

The *symptoms* are usually sudden in onset and are rarely delayed more than a few hours The extent of the paralysis will depend on the site of the hemorrhage At the level of the lesion there is loss of pain heat and cold and, if the hemorrhage has extended into the anterior horn cells signs of involvement of those parts Pyramidal tract signs usually occur below the level of the lesion, due either to the extension of the hemorrhage or to edema of the cord Sphincter disturbances occur at this stage and trophic and vasomotor signs may also be seen Signs of a complete transverse lesion may exist

Sudden death may occur if the lesion is a high one Some patients may recover completely, but some of them show residual conditions which are found at the point of greatest involvement of the spinal cord The symptoms due to edema of the cord clear up, but those due to hemorrhage are slow in disappearing and some of the symptoms may persist Syringomyelia may develop in a person who has been the victim of hematomyelia

The *diagnosis* in hematomyelia is made by the history of injury the absence of vertebral injury and the signs and symptoms enumerated above

The *treatment* of injuries to the cord should be conservative If the spinal cord has been injured by fracture or a fracture dislocation it is unlikely that the surgical intervention will bring about the recovery of the individual unless there is a spinal block proved by roentgen ray to be due to bony compression and not relieved by manipulative measures Operation in the stage of shock is absolutely contraindicated it certainly hastens the death of a number of these patients Competent nursing a sponge rubber mattress bed the use of an indwelling catheter with tidal drainage and careful regulation of the gastro intestinal tract are important things in the care of these patients Fresh air and sunshine the prevention of deformity passive movements especially to the large joints light general massage and extreme care of the skin will aid greatly the chances of recovery Attention should also be directed toward maintaining a normal blood protein level and providing an adequate vitamin intake

## AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis is a relatively rare disease involving the motor system

massage, orthopedic correction of any contractures or deformities and plenty of fresh air and sunshine are adjuncts in the treatment of this condition

## SYRINGOMYELIA

The term signifies an abnormal cavity in the spinal cord which is usually due to a congenital anomaly affecting the central canal Spinal gliosis produces the picture of syringomyelia because cavities are produced by the new growth especially in the central part of the cord Hematomyelia and hypertrophic cervical pachymeningitis may also lead to cavitation within the cord and produce symptoms somewhat similar to those of syringomyelia The level of the cord usually affected first is the lower cervical and upper dorsal

*Symptoms* — The early symptoms of syringomyelia are usually referable to the hands and consist of a loss of pain, heat and cold sensations and atrophy Due to a loss of pain sensation the patient frequently burns himself without experiencing discomfort and may have pathologic fractures without pain If the cavity spreads longitudinally the loss of sensation in the upper extremities becomes greater and will ultimately involve them entirely and later implicate part of the trunk If the descending root of the fifth nerve is implicated the loss of pain heat and cold may occur in the face Trophic disorders such as arthropathies painless felons pathologic fractures and bone necrosis, spontaneous amputation of the tips of the fingers and thickening of the fingers are seen Hemiatrophy of the face rarely occurs and is most likely due to sympathetic involvement Scoliosis and kyphoscoliosis in the cervical and dorsal regions are usually found If the cavity spreads high enough to involve the bulb signs of bulbar palsy due to syringobulbia may exist If it spreads transversely the pyramidal tracts are implicated and signs of this involvement are found below the level of the lesion The disease may be associated with other congenital deformities

The *differential diagnosis* should not be difficult if one remembers that a dissociated loss of sensation for pain heat and cold with preservation of touch and proprioceptive sensation is found at the level of the cavity along with anterior horn symptoms in the upper extremities and pyramidal tract symptoms in the lower extremities *The prognosis for cure is bad, but for life is good*, some cases continuing from twenty-five to fifty years

There is no drug which has any merit in the *treatment* of syringomyelia Radium and roentgen ray have been used with slight success Operative treatment for this has been recommended The cord is exposed and an opening made into the cavity (myelotomy) In our experience, the results of *operation are very unsatisfactory*

## MYELITIS

The spinal cord may be the seat of inflammation secondary to certain infectious diseases or may be a primary site of infection This condition is known as myelitis In degenerative and other noninfectious conditions the term myelopathy should be *more properly applied* Probably the commonest cause of myelitis is syphilis Trauma is not a cause of myelitis except in so far as it produces hemorrhage into the cord (*v* hematomyelia)

*Pathology* —When an entire section of the cord is involved it is referred to as transverse myelitis The inflammatory areas may be present in patches and be of a diffuse nature or they may be limited to one side of the cord and produce a Brown-Sequard paralysis The cord in myelitis on gross examination is softened and shrunken The spinal cord removed from rapidly fatal cases is of almost a putty consistency The vessels are the seat of round cell infiltration The ganglion cells are distorted and swollen as are also the myelin sheaths and the axis cylinders Fatty degeneration ensues and there is an accumulation of glia cells Microscopic examination shows descending and ascending degeneration of a secondary nature The meninges are frequently considerably involved especially in the syphilitic type

*Symptoms* —These will vary according to the location of the lesion and its severity During or shortly after an acute infection the

which produces *pernicious anemia* is responsible It is unlikely that the anemia itself causes the cord changes, because of *the fact that one occasionally sees combined* sclerosis before any change whatsoever has occurred in the blood The cord *implication* may take place during a remission of the blood picture As the disease progresses the entire white matter of the cord may be involved The disease used to be much more frequent than multiple sclerosis amyotropic lateral sclerosis, syringomyelia and chronic progressive spinal muscular atrophy, but now is infrequently seen probably due to the frequent nonspecific use of liver extract in general medicine and also to the improved quality of food eaten

*Symptoms* —The symptomatology varies somewhat, according to the parts of the cord diseased In the usual run of cases the following is the order in which the symptoms occur Paresthesias in the fingers and toes are an extremely common early symptom although the paresthesias may be limited either to the hands or the feet While pain is uncommon the involuntary jerking of the lower extremities which frequently occurs may produce pain by the overaction of the muscles The gait becomes involved and is of the ataxic type with an element of spasticity in it The involvement of the pyramidal tracts produces a spastic weakness below the level of the lesion with the ordinary signs of such disease If the sclerotic patches in the posterior columns are pronounced and occur at the level of the reflex arc, that particular reflex may be abolished even though the voluntary motor system be affected Sphincter disturbances and a girdle sensation may occur but if they do it is usually late in the course of the disease The results of physical examination of the nervous system *in the typical* case not far advanced will show pyramidal tract signs loss of the forms of sensation carried upward by the long fibers in the posterior columns *i e* sense of position of vibration and of tactile discrimination This may occasionally occur in other conditions, but is very characteristic of the combined sclerosis of pernicious anemia If the cervical cord is involved ataxia in the finger to-nose test, astereognosis and the other posterior column symptoms may be seen in the upper extremities Signs of peripheral nerve involvement are found in 25 to 40 per cent of the cases Pupillary disturbances and ocular palsies practically never occur The optic nerves are not usually affected, although rarely optic neuritis may be seen in pernicious anemia

Mental symptoms not uncommonly appear the patients are often garrulous, disorientated their memory fails and depression and delusions may be seen It is important to know that the mental symptoms and the spinal cord changes may occur before the anemia or during a remission The patient should be examined thoroughly from a general medical standpoint for the signs and symptoms of pernicious anemia if he presents on neurologic examination pyramidal tract and posterior column signs Before the advent of vitamin $B_{12}$ therapy the outlook was usually bad and the patient lived not more than three years Now the expectation of life is much greater and some of the nervous symptoms may be brought under control and the patient s life accordingly prolonged and physical signs of cord involvement actually disappear if treatment is begun early

The *differential diagnosis* is to be made from tabes peripheral neuritis posterolateral sclerosis of syphilis pellagra multiple sclerosis and tumor of the cord The singling out of the posterior and *lateral columns* without producing pain pupillary and ocular disturbances the negative tests for syphilis the absence of a spinal block *and the presence* of achlorhydria and a megaloblastic anemia should lead the diagnostician to a *correct conclusion*

The *treatment* is that of pernicious anemia but the action must be vigorous and prompt Liver and/or vitamin $B_{12}$ are indicated Folic acid is of no value because cord changes may become aggravated although the anemia improves It must be emphasized to the patient that treatment must be continued indefinitely otherwise relapse will occur Careful nursing the prevention of bed sores by cleanliness the use of an air bed or water bed and the prevention of infection of the genito-urinary system are important points to be considered Light

massage, orthopedic correction of any contractures or deformities and plenty of fresh air and sunshine are adjuncts in the treatment of this condition

## SYRINGOMYELIA

The term signifies an abnormal cavity in the spinal cord which is usually due to a congenital anomaly affecting the central canal Spinal gliosis produces the picture of syringomyelia because cavities are produced by the new growth especially in the central part of the cord Hematomyelia and hypertrophic cervical pachymeningitis may also lead to cavitation within the cord and produce symptoms somewhat similar to those of syringomyelia The level of the cord usually affected first is the lower cervical and upper dorsal

*Symptoms* —The early symptoms of syringomyelia are usually referable to the hands and consist of a loss of pain heat and cold sensations and atrophy Due to a loss of pain sensation the patient frequently burns himself without experiencing discomfort and may have pathologic fractures without pain If the cavity spreads longitudinally the loss of sensation in the upper extremities becomes greater and will ultimately involve them entirely and later implicate part of the trunk If the descending root of the fifth nerve is implicated the loss of pain heat and cold may occur in the face Trophic disorders such as arthropathies painless felons pathologic fractures and bone necrosis spontaneous amputation of the tips of the fingers and thickening of the fingers are seen Hemiatrophy of the face rarely occurs and is most likely due to sympathetic involvement Scoliosis and kyphoscoliosis in the cervical and dorsal regions are usually found If the cavity spreads high enough to involve the bulb signs of bulbar palsy due to syringobulbia may exist If it spreads transversely the pyramidal tracts are implicated and signs of this involvement are found below the level of the lesion The disease may be associated with other congenital deformities

The *differential diagnosis* should not be difficult if one remembers that a dissociated loss of sensation for pain heat and cold with preservation of touch and proprioceptive sensation is found at the level of the cavity along with anterior horn symptoms in the upper extremities and pyramidal tract symptoms in the lower extremities The prognosis for cure is bad but for life is good, some cases continuing from twenty-five to fifty years

There is no drug which has any merit in the *treatment* of syringomyelia Radium and roentgen ray have been used with slight success Operative treatment for this has been recommended The cord is exposed and an opening made into the cavity (myelotomy) In our experience the results of operation are very unsatisfactory

## MYELITIS

The spinal cord may be the seat of inflammation secondary to certain infectious diseases or may be a primary site of infection This condition is known as myelitis In degenerative and other noninfectious conditions the term myelopathy should be more properly applied Probably the commonest cause of myelitis is syphilis Trauma is not a cause of myelitis except in so far as it produces hemorrhage into the cord (r hematomyelia)

*Pathology* —When an entire section of the cord is involved it is referred to as transverse myelitis The inflammatory areas may be present in patches and be of a diffuse nature or they may be limited to one side of the cord and produce a Brown-Sequard paralysis The cord in myelitis on gross examination is softened and shrunken The spinal cord removed from rapidly fatal cases is of almost a putty consistency The vessels are the seat of round-cell infiltration The ganglion cells are distorted and swollen as are also the myelin sheaths and the axis cylinders Fatty degeneration ensues and there is an accumulation of glia cells Microscopic examination shows descending and ascending degeneration of a secondary nature The meninges are frequently con considerably involved especially in the syphilitic type

*Symptoms* —These will vary according to the location of the lesion and its severity During or shortly after an acute infection the

which produces pernicious anemia is responsible It is unlikely that the anemia itself causes the cord changes because of the fact that one occasionally sees combined sclerosis before any change whatsoever has occurred in the blood The cord implication may take place during a remission of the blood picture As the disease progresses the entire white matter of the cord may be involved The disease used to be much more frequent than multiple sclerosis amyotropic lateral sclerosis syringomyelia and chronic progressive spinal muscular atrophy, but now is infrequently seen probably due to the frequent nonspecific use of liver extract in general medicine and also to the improved quality of food eaten

*Symptoms* —The symptomatology varies somewhat, according to the parts of the cord diseased In the usual run of cases the following is the order in which the symptoms occur Paresthesias in the fingers and toes are an extremely common early symptom although the paresthesias may be limited either to the hands or the feet While pain is uncommon the involuntary jerking of the lower extremities, which frequently occurs may produce pain by the overaction of the muscles The gait becomes involved and is of the ataxic type with an element of spasticity in it The involvement of the pyramidal tracts produces a spastic weakness below the level of the lesion with the ordinary signs of such disease If the sclerotic patches in the posterior columns are pronounced and occur at the level of the reflex arc that particular reflex may be abolished even though the voluntary motor system be affected Sphincter disturbances and a girdle sensation may occur but if they do it is usually late in the course of the disease The results of physical examination of the nervous system in the typical case not far advanced will show pyramidal tract signs loss of the forms of sensation carried upward by the long fibers in the posterior columns *i e* sense of position of vibration and of tactile discrimination This may occasionally occur in other conditions but is very characteristic of the combined sclerosis of pernicious anemia If the cervical cord is involved ataxia in the finger-to-nose test, astereognosis and the other posterior column symptoms may be seen in the upper extremities Signs of peripheral nerve involvement are found in 25 to 40 per cent of the cases Pupillary disturbances and ocular palsies practically never occur The optic nerves are not usually affected, although rarely optic neuritis may be seen in pernicious anemia

Mental symptoms not uncommonly appear the patients are often garrulous disorientated their memory fails and depression and delusions may be seen It is important to know that the mental symptoms and the spinal cord changes may occur before the anemia or during a remission The patient should be examined thoroughly from a general medical standpoint for the signs and symptoms of pernicious anemia if he presents on neurologic examination pyramidal tract and posterior column signs Before the advent of vitamin $B_{12}$ therapy the outlook was usually bad and the patient lived not more than three years Now the expectation of life is much greater and some of the nervous symptoms may be brought under control and the patient's life accordingly prolonged and physical signs of cord involvement actually disappear if treatment is begun early

The *differential diagnosis* is to be made from tabes peripheral neuritis posterolateral sclerosis of syphilis pellagra multiple sclerosis and tumor of the cord The singling out of the posterior and lateral columns without producing pain pupillary and ocular disturbances the negative tests for syphilis the absence of a spinal block and the presence of achlorhydria and a megaloblastic anemia should lead the diagnostician to a correct conclusion

The *treatment* is that of pernicious anemia but the action must be vigorous and prompt Liver and/or vitamin $B_{12}$ are indicated Folic acid is of no value because cord changes may become aggravated although the anemia improves It must be emphasized to the patient that treatment must be continued indefinitely otherwise relapse will occur Careful nursing the prevention of bed sores by cleanliness the use of an air bed or water bed and the prevention of infection of the genito-urinary system are important points to be considered Light

not known but at the Philadelphia General Hospital the commonest conditions found at autopsy were syphilis and tuberculosis

The earliest *symptom* is pain of a root nature, which occurs at the level of the lesion This is followed by compression of the anterior roots or disease of the anterior horn cells which produces atrophic paralysis at the level In view of the fact that the lower cervical cord is more frequently affected the foregoing symptoms are first seen in the upper extremities especially the hands Horner's syndrome may occur from involvement of the eighth cervical and first dorsal roots As the condition progresses, the signs of compression of the cord occur with interruption of the functions of the sensory paths and of the pyramidal system Disturbance of the sphincters is also seen

If the process is syphilitic in origin other signs of neurosyphilis may be present Spinal tumor syringomyelia and caries of the spine will have to be differentiated

## FRIEDREICH'S ATAXIA

Family or hereditary ataxia is a rare chronic, progressive heredodegenerative disease of the nervous system beginning as a rule before the age of ten or twelve years It is more common in males and affects chiefly the posterior columns spino-cerebellar tracts and the pyramidal tracts and is associated at times with an atrophy or agenesis of the cerebellum The *symptoms* are ataxia loss of the deep reflexes although they may occasionally be exaggerated Babinski's sign dysarthria often of the scanning type nystagmus Club foot pes cavus Friedreich's toe which consists of extension of the first phalanx of the great toe with flexion of the second to a right angle, and scoliosis make up the physical deformities Occult spina bifida may also be seen If the disease is of long standing atrophy due to disease of the anterior horn cells may occur in the upper extremities The so-called Marie's hereditary cerebellar ataxia resembles Friedreich's ataxia in many ways except that it occurs after twenty or thirty years of age and is not so likely to be associated with skeletal defects

The greatest difficulty in *differential diagnosis* will be with juvenile tabes which will show the characteristic pupillary state and areflexia laboratory signs of syphilis and the absence of skeletal deformities although Charcot's joints and trophic ulcers may be seen Multiple sclerosis may be mistaken for Friedreich's ataxia although the former is very rare in childhood

*Treatment* of Friedreich's ataxia and Marie's hereditary cerebellar ataxia is unavailing Marriage of members of families in which Friedreich's disease is known to exist is ill advised but in cases of Marie's ataxia a familial history is rare

## DISEASE OF THE BLOOD VESSELS OF THE SPINAL CORD

Either of the arterial systems of the spinal cord posterior or anterior may be occluded as a result of the disease which is most frequently syphilis The free flow of blood through the vessels may also be interfered with because of tumors, either benign or malignant especially the latter It is also likely that the sudden paralysis which sometimes takes place in Pott's disease or carcinoma of the spine may be due to interference with the vascular system particularly the venous drainage The most outstanding symptoms therefore will be referable to the parts of the cord involved Sometimes however pyramidal tract signs are seen below the level of the lesion and there may be dissociated sensory loss (A Ornsteen) The arteries in the posterior aspect of the cord are more frequently involved than those of the anterior The usual cause is syphilis

## HERPES ZOSTER (ZONA OR SHINGLES)

Herpes zoster is an affection of the sensory spinal or cranial ganglia There are two types of herpes zoster one of primary viral origin which may even occur in epidemics the other due to secondary involvement of the ganglia by such conditions as syphilis tumor or perhaps by acute infectious disease It may be due to anything which can affect a sensory ganglion which is frequently the site of hemorrhage and destruction Secondary degeneration may occur both in the peripheral nerve and in the dorsal root

If the condition is due to an acute infection the *symptoms* may be of a general nature such as fever headache and malaise The first symptom is pain which is of a definite root nature and in the root distribution In many cases it is sharp and unbearable If the patient is examined at this stage it will be seen that there is hyperesthesia and perhaps a loss of pain sense in the distribution

patient may develop pain in his back often accompanied by a girdle sensation If the disease is localized to one or two segments pain, except at the level of the lesion, is not a common symptom but paresthesias frequently exist below the inflammatory reaction The involvement of the pyramidal tracts will produce the most alarming symptom as far as the patient is concerned and these signs usually run true to form Just as the deep reflexes are occasionally lost on the side paralyzed in apoplexy, so the deep reflexes may be lost in myelitis early in the history of the case, but they later usually become exaggerated The Babinski sign, ankle clonus and perhaps patellar clonus soon appear If the posterior columns are involved there will be a loss of sense of position, vibration and tactile discrimination, and disease of the anterolateral tracts will result in loss of pain heat and cold All reflexes at the level of the lesion will be abolished Disturbances of function of the sphincters are extremely common, the usual history is that there is first retention and then incontinence of urine Due to the difficulty in the control of the bladder infection of the urinary tract occurs frequently complicates the case and lessens the possibility of recovery While there may be incontinence of feces most cases have marked constipation Occasionally priapism is a symptom Trophic disorders, such as loss of sweat secretion rarely increase of sweat various vasomotor phenomena and bed sores, occurring especially over the heels and the sacrum are common symptoms Involuntary jerkings of the lower extremities with reflexes of defense (Sinkler s toe phenomenon) are frequently seen in severe forms and are sometimes mistaken for return of power The recovery of the patient depends in a large measure upon the prevention of bladder infection and bed sores Many patients do extremely well Others make no improvement and remain bedfast Extreme degrees of flexion may occur after the paralysis has existed for some months

Complete transverse lesions of the cord have followed the intrathecal injection of sulfanilamide penicillin streptomycin spinal anesthetics, and alcohol

The *diagnosis* is made by the history and a *more or less rapidly* occurring paralysis and loss of sensation below a definite level accompanied by paralysis of the sphincters Multiple sclerosis occasionally has a sudden onset sudden paralysis of the lower extremities may be the first symptom of that disease

The *treatment* is largely symptomatic The patient should be placed in bed and an air mattress or water mattress used Extreme care should be taken of the skin which should be bathed often with alcohol and powdered with a mild antiseptic Frequent change of position to prevent constant pressure on one particular point is imperative The fact that the patient is incontinent of urine makes the nursing job an extremely arduous one, inasmuch as the bed linen should be changed whenever it is soiled Catheterization should be postponed as long as possible Daily irrigation of the bladder with a mild antiseptic may be necessary The use of tidal drainage and urinary antiseptics especially sulfa drugs and antibiotics is probably the bladder treatment of choice A daily enema will usually be necessary and occasionally a laxative should be given The lower extremities should be protected with a cradle and a good position at the large joints maintained if necessary with splints Daily passive movements to the large joints is also indicated Hydrotherapy and physiotherapy are of service when the patient begins to recover and will serve to relieve the spasticity in the lower extremities The body nutrition should be maintained a high protein diet with supplemental vitamins should be given and the serum protein level checked from time to time

## HYPERTROPHIC CERVICAL PACHYMENINGITIS

As the name indicates this is a thickening of the membranes especially the dura which may readily be twelve times the normal thickness The thickening of the dura is intense and causes the meninges to adhere to each other as well as to the roots and the spinal cord The cord is compressed and later on may be the seat of a rim degeneration secondary degeneration and even cavitation While the lower part of the cervical cord is most frequently involved the process may extend to include the entire cord and even the medulla and pons The exact etiologic factor is

Epidemics usually occur during the summer and early fall months and the incidence drops off abruptly about the time of the first frost. Sporadic cases occur, however, throughout the year. The sexes are about equally involved. The great majority of cases are children but adults likewise are affected, possibly more so in recent years. When poliomyelitis occurs in pregnant women transmission to the fetus is very rare.

*Pathology.*—The anterior horn cells of the spinal cord, the nuclei of the motor cranial nerves, and the meninges are chiefly involved. Occasionally changes are noted in the motor cortex, white matter, basal ganglia and cerebellum. The characteristic pathologic change is that of hyperemia, edema and perivascular round-cell infiltration. The anterior horn cells, particularly those in the lumbar and cervical areas, are swollen, show chromatolysis and marked neuronophagia. In severe cases many of the anterior horn cells disappear and are replaced by glial cells and ultimately the motor nerve roots, nerves and muscles become atrophic. In addition to the changes in the nervous system hyperplasia of the lymphoid tissue throughout the body occurs.

*Symptoms.*—The clinical picture tends to be quite variable. Cases are usually classified as abortive, nonparalytic, paralytic and bulbar.

The abortive type is the most frequent. The illness may be so mild that it passes unrecognized. In other cases there is a sudden onset with a fever of 101 to 102, malaise, headache, sore throat, anorexia, constipation or occasionally diarrhea and vomiting. The neurologic examination is negative and the spinal fluid may show no alteration. The symptoms subside within 24 to 72 hours and the patient thereafter is well and without residua. In the absence of an epidemic such cases are often considered as merely acute upper respiratory or gastrointestinal infections and poliomyelitis is seldom considered. However, during epidemics it is possible that many cases described as being of the abortive type are not actually poliomyelitis.

About half the severe cases run a biphasic or dromedary febrile course. A brief mild nonspecific illness of short duration clinically closely akin to the abortive type is followed by apparent recovery. After four to seven days fever and headache along with signs of central nervous system involvement appear. In other and more typical cases the headache and fever continue. Occasionally one sees a patient with hyperesthesia who resents being disturbed. Pain in the trunk and limbs may be present along with localized muscle and nerve trunk tenderness. Slight muscle twitchings may be noted. Retraction of the head, nuchal and spinal rigidity and Kernig's sign are usually present. In some cases apathy, drowsiness and stupor occur. There may be retention of urine and rarely convulsions. In the nonparalytic cases the symptoms subside; in others the development of paralysis ushers in the paralytic phase.

While any part of the spinal cord may be involved in the ordinary type of the disease, the lumbo-sacral region is most frequently affected and usually in an irregular manner. The paralysis, which is a flaccid one, will depend upon the anterior horn segments involved and will be in the distribution of those segments. The muscles of the abdomen, the back and even those of the neck may be paralyzed. Certain writers believe that the commonest cause of scoliosis is poliomyelitis. An entire extremity or a part of it may be paralyzed and the involvement may be so irregular as to produce a paralysis of an upper and the opposite lower extremity.

The paralysis is accompanied by a loss of the deep and superficial reflexes in the segments involved, and after a week or two there may be loss of contractibility of the muscles to faradism and galvanism, and in severe cases complete reactions to degeneration. As a rule the height of the paralysis is reached within three to five days of the onset. In many cases, especially infants, the exact date of paralysis is not known. Some of the cases described under the heading of Landry's paralysis are in reality instances of poliomyelitis. Involvement of the bulb or of the ocular nuclei may occur either as distinct types of the disease or as part of the general picture. The virus of poliomyelitis can also affect the motor cortex, producing hemiplegia of the spastic type. To

of the root affected From a few hours to a few days after the onset of pain the skin throughout the entire course or a part of the course of the nerve becomes red and the site of vesicles The skin disturbance lasts a few days, although if infection occurs the skin lesions may not clear up for two or three weeks Scarring and pigmentation especially the latter, may appear and persist After the eruption has taken place pain may subside, but, on the other hand, the pain may persist This is especially so when the herpes involves the face or if it occurs in an elderly person While any part of the body may be affected herpes zoster most usually implicates the chest Geniculate ganglion herpes occurs in the ear and is usually accompanied by Bell s palsy The disease is practically always unilateral and recurrences are rare Corneal ulceration with secondary infection may occur in herpes of the ophthalmic division of the fifth nerve As an evidence of meningeal reaction lymphocytosis of the spinal fluid is seen Rarely paralysis due to implication of anterior roots with the usual signs of such involvement may develop The prognosis is good but intractable neuralgic pain may be an uncomfortable sequence

In considering the *treatment* it is important to find the cause for the condition The possibilities of spinal tumor, Pott s disease and neurosyphilis should be considered and eliminated Locally alcohol saturated with boric acid and frequently applied to the vesicles will cause them to dry up Aureomycin has been reported as being beneficial in relieving the pain in some cases Drugs such as acetylsalicylic acid acetphenetidin and perhaps even codeine or morphine may be necessary Obstetrical pituitrin 1 cc several times daily, thiamin frequent small pox vaccinations autohemotherapy and roentgen irradiation have also been recommended, but in some instances it may be necessary to do root block with novocaine or if this procedure fails to section the root involved

## ACUTE ANTERIOR POLIOMYELITIS

*Synonyms* —Infantile spinal paralysis Heine-Medin disease

*Definition* —Acute anterior poliomyelitis is an acute infectious disease of viral etiology with a predilection to involve the nervous system particularly the anterior horn cells and the nuclei of the motor cranial nerves It occurs endemically but more frequently as an epidemic disease especially during the summer months Although adults are not spared the disease more frequently occurs in children

*Etiology and Epidemiology* —The infectious agent in a filterable virus Much remains to be learned regarding the natural mode of transmission The virus probably enters the body by way of the upper gastrointestinal tract including the mouth and pharynx It has been isolated from the pharynx just prior to the onset and during the first few days of symptoms and from the stools four to six weeks or more after the onset Once the infectious agent has gained access to the body it spreads to the central nervous system probably by way of the lymphatics The incubation period is not exactly known but is probably about ten days to two weeks Healthy human carriers who harbor the virus but never show symptoms are frequently encountered during epidemics Dissemination of the disease may occur by direct contact through carriers or by contact with contaminated objects such as food and sewage During an epidemic the virus has been isolated from flies and it is possible that insects may be a vector it is also found in high concentrations in sewage from areas where the number of clinical cases is large The virus varies in infectivity Although multiple cases within the same family occur with fair frequency, usually only one member is infected and the incidence in nurses physicians and others who come into close contact with active cases is relatively rare There is some evidence to suggest that severe muscular exercise immediately prior to exposure to the infectious agent may contribute to the development of a severe form of the disease and robust children have no greater immunity than the markedly undernourished Bulbar types of the disease occur frequently in children whose tonsils have been removed during an epidemic

Epidemics usually occur during the summer and early fall months and the incidence drops off abruptly about the time of the first frost Sporadic cases occur however throughout the year The sexes are about equally involved The great majority of cases are children but adults likewise are affected possibly more so in recent years When poliomyelitis occurs in pregnant women transmission to the fetus is very rare

*Pathology* —The anterior horn cells of the spinal cord the nuclei of the motor cranial nerves and the meninges are chiefly involved Occasionally, changes are noted in the motor cortex white matter basal ganglia and cerebellum The characteristic pathologic change is that of hyperemia, edema and perivascular round-cell infiltration The anterior horn cells particularly those in the lumbar and cervical areas are swollen show chromatolysis and marked neuronophagia In severe cases many of the anterior horn cells disappear and are replaced by glial cells and ultimately the motor nerve roots nerves and muscles become atrophic In addition to the changes in the nervous system hyperplasia of the lymphoid tissue throughout the body occurs

*Symptoms* —The clinical picture tends to be quite variable Cases are usually classified as abortive nonparalytic paralytic and bulbar

The abortive type is the most frequent The illness may be so mild that it passes unrecognized In other cases there is a sudden onset with a fever of 101° to 102 malaise headache sore throat anorexia constipation or occasionally diarrhea and vomiting The neurologic examination is negative and the spinal fluid may show no alteration The symptoms subside within 24 to 72 hours and the patient thereafter is well and without residua In the absence of an epidemic such cases are often considered as merely acute upper respiratory or gastro intestinal infections and poliomyelitis is seldom considered However during epidemics it is possible that many cases described as being of the abortive type are not actually poliomyelitis

About half the severe cases run a biphasic or dromedary febrile course A brief mild nonspecific illness of short duration clinically closely akin to the abortive type, is followed by apparent recovery After four to seven days fever and headache along with signs of central nervous system involvement appear In other and more typical cases the headache and fever continue Occasionally one sees a patient with hyperesthesia who resents being disturbed Pain in the trunk and limbs may be present along with localized muscle and nerve trunk tenderness Slight muscle twitchings may be noted Retraction of the head nuchal and spinal rigidity and Kernig s sign are usually present In some cases, apathy drowsiness and stupor occur There may be retention of urine and rarely convulsions In the non paralytic cases the symptoms subside in others the development of paralysis ushers in the paralytic phase

While any part of the spinal cord may be involved in the ordinary type of the disease the lumbo-sacral region is most frequently affected and usually in an irregular manner The paralysis which is a flaccid one will depend upon the anterior horn segments involved and will be in the distribution of those segments The muscles of the abdomen the back and even those of the neck may be paralyzed Certain writers believe that the commonest cause of scoliosis is poliomyelitis An entire extremity or a part of it may be paralyzed and the involvement may be so irregular as to produce a paralysis of an upper and the opposite lower extremity

The paralysis is accompanied by a loss of the deep and superficial reflexes in the segments involved and after a week or two there may be loss of contractibility of the muscles to faradism and galvanism and in severe cases *complete reactions to degeneration* As a rule the height of the paralysis is reached within three to five days of the onset In many cases especially infants the exact date of paralysis is not known Some of the cases described under the heading of Landry s paralysis are in reality instances of poliomyelitis Involvement of the bulb or of the ocular nuclei may occur either as distinct types of the disease or as part of the general picture The virus of poliomyelitis can also affect the motor cortex producing hemiplegia of the spastic type To

this condition the term of polioencephalitis is applied The involvement of the cranial nerves will produce paralysis in the distribution of the nuclei affected Meningitic types in which Kernig's sign stiff neck and pain on manipulation of the paralyzed extremity predominate, are frequent Tenderness on percussion over the side of the pathologic process may be found Cerebellar symptoms due either to involvement of the cerebellum or of the cerbellar peduncles, may occasionally be encountered Those patients with involvement of the bulb not infrequently die suddenly Loss of sensation does not occur The bladder may be paralyzed Trophic lesions and bed sores are extremely uncommon complications, although the skin of the paralyzed extremity may be cool mottled and show disturbance of sweat secretion

*Bulbar Type* —In the bulbar type the most frequent nerves involved are the 7th 9th, 10th, 11th, and 12th The early signs therefore are inability to swallow collection of saliva in the posterior pharynx the speech has a nasal twang fluid regurgitates through the nose Facial paralysis of one or both sides may occur

In the acute and paralytic phases, the leukocytes in the blood are usually not increased a few cases may show leucocytosis The spinal fluid is usually not under increased pressure, is clear shows excessive total protein which is of diagnostic importance, and has a normal percentage of sugar A mild alteration of the colloidal-gold curve may be seen The cells are definitely increased from 10 to a few hundred Though polymorphonuclear leukocytes predominate in the early stage of the disease, they quickly give way to lymphocytes

Following the onset of paralysis and the subsidence of the signs of infection the muscle tenderness gradually disappears and the convalescent phase begins Those muscles whose anterior horn cells are permanently damaged will begin to atrophy and show the reaction of degeneration while other muscles may begin to show some signs of returning function In many cases the residual paralysis may be much less than would it first appear since many anterior horn cells are only temporarily disturbed and may recover function The duration of the convalescent phase varies with the individual case but improvement may continue for as long as eighteen months

The chronic stage represents the end result of the disease The affected muscles are atrophied, the deep reflexes are absent and muscle power is impaired Flaccid palsies or paralyses contractures, and deformities such as scoliosis, lordosis and talipes equinus may be noted along with various trophic changes The skin over the paralyzed muscles may be cold dry and cyanotic the paralyzed limb may show varying degrees of dysgenesis

*Diagnosis* —Once the disease is in full bloom but little diagnostic difficulty will be encountered In abortive pre paralytic and mild non paralytic stages the problem may be more difficult In times of an epidemic all illnesses characterized by fever headache gastrointestinal symptoms, sore neck or back and muscle tenderness should be regarded with suspicion as possible cases of poliomyelitis but other conditions should be also considered Pott s disease hip disease meningitis of any type encephalitis lymphocytic choriomeningitis acute infectious neuronitis and infantile scurvy are often mistaken for acute anterior poliomyelitis The so-called pink disease may also be wrongly diagnosed poliomyelitis Rheumatic fever may be mistaken for infantile paralysis Occasionally during epidemics of infantile paralysis instances of widespread involvement of the white matter of the cord may be seen and the picture of myelitis rather than poliomyelitis results

The spinal fluid findings may be helpful but are not essential to the diagnosis since the spinal fluid may be normal in abortive cases and may even remain normal in non paralytic and paralytic cases

*Prognosis* —The prognosis varies in different epidemics the mortality being from 5 to 25 per cent Extreme restlessness and apprehension sometimes connote a poor prognosis The most unfavorable cases are those with bulbar symptoms in which the mortality rate is usually greater than 50 per cent It is impossible to predict whether paralysis will occur in a given case or if it

does, how extensive will be the residual deformity It is certainly true that there are many cases of acute poliomyelitis which are extremely mild and never develop paralysis When paralysis has occurred, it may clear up rapidly or no improvement may occur However it is important to keep the flag flying and to be optimistic as to the amount of recovery possible As in any paralysis of the peripheral nerve or anterior horn type, the early return of normal reactions to galvanism or faradism is a good prognostic omen Less than 25 per cent of the patients with the paralytic form suffer severe permanent disability, about 25 per cent have mild disabilities while over half recover without residua The mortality rate varies from 1 to 10 per cent of the total number of cases

*Prevention* —Since the mode of spread of the disease is unknown no definite preventive precautions can be established However, during epidemics the following measures are advisable All known cases should be isolated usually for a three week period Contact with patients suffering from unexplained minor illnesses should be avoided Personal cleanliness should be carefully maintained particularly the hands should be washed before eating Elective tonsillectomies and tooth extractions should be avoided Fatigue and extreme overexertion should be guarded against Food should be protected from flies Swimming in water which may be contaminated by sewage is to be avoided

*Treatment* —There is no specific treatment for the disease and no drug or antibiotic at present available is of value Convalescent serum at one time was extensively used but experience has shown it to be without beneficial effect and given into the subarachnoid space may grossly aggravate the disease Plasma likewise is useless Until such a time as specific measures become available therapy must be symptomatic and supportive

Usually bed rest an adequate fluid intake and a light nutritious diet along with proper care of elimination are adequate in the management of patients with the abortive or mild non paralytic types The importance of rest is to be stressed since undue physical exertion in the early stages of the disease appears to precipitate paralysis In the more severe stages of the disease the patient should be made as comfortable as possible Mild sedatives and analgesics may be indicated An adequate fluid intake should be maintained and the bowels should be kept open by enemas or mild purgatives Urinary retention should be treated by the administration of prostigmine or other parasympathetic stimulants Boards under the bed and foot boards are of help in preventing undue deformities when paralysis develops Early splinting is to be avoided Hot packs may be helpful in relieving the pain and discomfort Curare and prostigmine are used in some clinics to relieve muscle spasm Personally we have not found them of value

The Kenny treatment has attracted far greater attention than it warrants Its only value lies in its stress on the advantages of early physiotherapy and the avoidance of too early splinting the latter treatment being advised by orthopedists and not by neurologists

Respiratroy failure due to either paralysis of the muscles of respiration or to involvement of the respiratory center in the medulla requires vigorous therpeutic measures In respiratory muscle paralysis the Drinker respirator may be lifesaving but it is of no value and may even be harmful when respiratory difficulties are due to bulbar involvement With respiratory embarrassment prophylactic penicillin to prevent pneumonia should be administered When respiratory failure is due to bulbar involvement continuous inhalation of a humidified mixture of 95 per cent $O_2$ and 5 per cent $CO_2$ is of value and the tracheal airway must be kept patent by the use of a suction apparatus and postural drainage Bulbar involvement may be treated by tracheotomy the insertion of a tracheal tube and the administration of continuous oxygen Again the airway must be kept free by suction The patient s fluid and nutritive requirements must not be forgotten Parenteral fluid should be given A liquid diet high in calories may be given by tube with due care being taken to prevent aspiration following regurgitation or vomiting

this condition the term of polioencephalitis is applied. The involvement of the *cranial* nerves will produce paralysis in the distribution of the nuclei affected. *Meningitic* types in which Kernig's sign, stiff neck and pain on manipulation of the *paralyzed* extremity predominate, are frequent. Tenderness on percussion over the *side of the* pathologic process may be *found*. Cerebellar symptoms, due either to involvement of the cerebellum or of the *cerbellar peduncles* may occasionally be encountered. Those patients with involvement of the bulb not infrequently die suddenly. Loss of sensation does not occur. The bladder may be paralyzed. Trophic lesions and bed sores are extremely uncommon complications although the skin of the paralyzed extremity may be *cool, mottled and* show disturbance of sweat secretion.

*Bulbar Type*.—In the bulbar type the most frequent nerves involved are the 7th, 9th, 10th, 11th, and 12th. The early signs *therefore are inability to* swallow, collection of saliva in the posterior pharynx, the speech has a nasal twang, fluid regurgitates through the nose. Facial paralysis of one or both sides may occur.

In the acute and paralytic phases the leukocytes in the blood are usually not increased, a few cases may show leucocytosis. The spinal fluid is usually not under increased pressure, is clear, shows excessive total protein, which is of diagnostic importance, and has a normal percentage of sugar. A mild alteration of the colloidal gold curve may be seen. The cells are definitely increased from 10 to a few hundred. Though polymorphonuclear leukocytes predominate in the early stage of the disease they quickly give way to lymphocytes.

Following the onset of paralysis and the subsidence of the signs of infection the muscle tenderness gradually disappears and the convalescent phase begins. Those muscles whose anterior horn cells are permanently damaged will begin to atrophy and show the reaction of degeneration while other muscles may begin to show some signs of returning function. In many cases the residual paralysis may be much less than would at first appear since many anterior horn cells are only temporarily disturbed and may recover function. The duration of the convalescent phase varies with the individual case but improvement may continue for as long as eighteen months.

The chronic stage represents the end result of the disease. The affected muscles are atrophied, the deep reflexes are absent and muscle power is impaired. Flaccid palsies or paralyses, contractures, and deformities such as scoliosis, lordosis and talipes equinus may be noted along with various *trophic changes*. The skin over the paralyzed muscles may be cold, dry and cyanotic, the *paralyzed limb* may show varying degrees of dysgenesis.

*Diagnosis*.—Once the disease is in full bloom but little diagnostic difficulty will be encountered. In abortive pre-paralytic and mild non-paralytic stages, the problem may be more difficult. In times of an epidemic all illnesses characterized by fever, headache, gastrointestinal symptoms, sore neck or back and muscle tenderness should be regarded with suspicion as possible cases of poliomyelitis, but other conditions should be also considered. Pott's disease, hip disease, meningitis of any type, encephalitis, lymphocytic choriomeningitis, acute infectious neuronitis and infantile scurvy are often mistaken for acute anterior poliomyelitis. The so-called pink disease may also be wrongly diagnosed poliomyelitis. Rheumatic fever may be mistaken for infantile paralysis. Occasionally during epidemics of infantile paralysis instances of widespread involvement of the white matter of the cord may be seen and the picture of myelitis rather than poliomyelitis results.

The spinal fluid findings may be helpful but are not essential to the diagnosis since the spinal fluid may be normal in abortive cases and may even remain normal in non-paralytic and paralytic cases.

*Prognosis*.—The prognosis varies in different epidemics, the mortality being from 5 to 25 per cent. Extreme restlessness and apprehension sometimes connote a poor prognosis. The most unfavorable cases are those with bulbar symptoms in which the mortality rate is usually greater than 50 per cent. It is impossible to predict whether paralysis will occur in a given case or if it

The vision may be disturbed in *multiple* sclerosis long before changes of the fields or eye grounds However with prolonged observation pallor of the disks especially of a bitemporal nature, may be found Impairment of the fields particularly central scotomas for color is often present and may occur in the absence of changes in the disks Ocular palsies are not as prominent as pallor of the disks and nystagmus The abdominal reflexes due to involvement of the pyramidal tracts disappear The symptoms of pseudobulbar palsy especially the emotional disturbance *and a general euphoric trend may* be seen

A frank psychosis is occasionally seen in multiple sclerosis and while it may take on the picture of a depression it is more often characterized by euphoria excitement and delusions If the patient with multiple sclerosis lives long enough, he may present the picture of complete dementia The blood Wassermann *is negative the spinal fluid* as a rule, shows a normal cell count normal globulin content and a negative Wassermann The colloidal gold curve sometimes shows an alteration of the first zone type or the curve may be high in the middle The disease which is slightly more common in males at one time was considered to be rare but in recent years its occurrence has not been *uncommon*

Remissions are common in the disease especially in those cases which begin acutely A remission may last from a few months to years The duration of life is from one to twenty five years the average being about ten

Although some patients suffering from multiple sclerosis become chair- or bed ridden in a few years *there are many cases* which run a benign course

*Diagnosis* —The conditions which may be confused with multiple sclerosis are disseminated neurosyphilis arteriosclerosis the combined sclerosis seen in pernicious anemia Friedreich s ataxia tumors of the cerebellum and the cerebellopontile angle tumors of the cord hysteria multiple areas of softening or diseased areas as the result of trauma and pseudosclerosis While some of these conditions undoubtedly will cause confusion at times mistakes in diagnosis can be kept to a *minimum The signs symptoms and laboratory* findings of neurosyphilis the blood picture and the gastric analysis in pernicious anemia signs and symptoms of a tumor should keep the record clear as far as these conditions are concerned Because of a remission which may apparently be brought about by psychotherapy, along with an initial onset during a period of emotional stress the diagnosis of hysteria is frequently made A careful examination with the elicitation of signs such as nystagmus and Babinski s sign which are always due to an organic involvement of the central nervous system should avoid the wrong diagnosis In the so-called acute multiple sclerosis a differential diagnosis is extremely hard to make between that form of disease and disseminated encephalomyelitis The mere fact that acute involvement of the nervous system of an apparent inflammatory type clears up does not rule out the possibility *that the case may be one of multiple* sclerosis

*Treatment* —There is no specific therapy for the disease Fever therapy iodides histamine quinine heparin and Dicumarol have all been tried without result The patient should be placed in the best possible health foci of infection removed and freedom from work and worry instituted A *high vitamin B diet, and intramuscular* liver injections are worthy of a trial Massage hydrotherapy and reeducation to keep the muscles and skin in good condition should greatly aid the patient Later on as the patient becomes chair or bed ridden careful nursing is required and the attending physician should be tactfully encouraging and should use as much constructive *psychotherapy as possible*

## THE BRAIN

### FOCAL SIGNS DUE TO LOCALIZED CEREBRAL LESIONS

Lesions of the *frontal lobe* produce as a rule some changes in the intellectual capacity of the individual Irritability, loss of memory undue jocosity and disorientation in space and position along with a loss of drive or initiative may characterize

In paralytic cases in the convalescent phase, physiotherapy in the form of gentle massage passive and active motion and muscle re-education exercises are of value Splints and braces may be necessary and helpful and nonparalyzed muscles should be strengthened It should ever be remembered that there is an inherent tendency for the paralyzed muscles to regain a considerable degree of function and spontaneous improvement may be expected to occur up to 18 months to two years after the acute illness In some epidemics as high as 85 per cent of the cases with paralysis may eventually show a practically complete return of muscle function

In old cases, orthopedic procedures may be indicated Occupational therapy is helpful not only in strengthening weak muscles but also in aiding the patient to acquire skills which may be economically valuable and in building and maintaining morale

## MULTIPLE SCLEROSIS

*Synonyms* —Disseminated sclerosis Insular sclerosis

This is a chronic disease of the central nervous system, although it may run an acute or subacute course The cause of the disease is not known Experimentally demyelination has been produced as an allergic response and possibly allergy plays some role in the causation In a few instances the disease may be familial occurring in siblings or in both parents and children It may follow after an acute infectious disease Apparently in some cases it has been precipitated by pregnancy Trauma produces a condition which simulates multiple sclerosis

The age at onset is usually between twenty and forty years, although cases do occur earlier and later in life In cases occurring in childhood, especially in more than one member of a family, one is more likely to be dealing with a familial disease of the extrapyramidal system

*Pathologically* the disease is distinguished by numerous sclerotic patches scattered through the central nervous system These patches are characterized by a degeneration of the myelin sheaths and a preservation of the axis cylinders which, however, are affected later The optic nerves are involved, usually in the nature of a retrobulbar neuritis The irregularity and the number of the sclerotic patches frequently makes for peculiar and bizarre symptoms The white matter of the central nervous system is much more affected than the gray The pyramidal tracts, due to their great length are practically always involved by sclerotic patches

*Symptoms* —The onset of the disease, while usually insidious, may be abrupt Sudden blindness, hemiplegia, crural paraplegia and an ocular palsy may come on quickly and clear up The preservation of the axis cylinders accounts for the return of power The history in the ordinary case is usually first of numbness parasthesia and weakness in the lower extremities, followed by ataxia and tremor in the upper extremities ocular disturbance and involvement of speech The ocular signs are dimness of vision blindness nystagmus or perhaps a palsy of an ocular nerve The classical *triad of Charcot* namely tremor scanning speech and nystagmus was at one time considered the chief symptoms in multiple sclerosis but it occurs only as a late manifestation in about 25 per cent of cases One should be extremely hesistant in diagnosing multiple sclerosis without the presence of pyramidal tract signs While sensory disturbances may be present one would expect to see such changes more often than they occur signs of posterior column disturbance are most common The type of sensory loss will depend upon the exact location of the sclerotic patch responsible for it The tremor which is called an intention or action tremor is made worse by movement While it is usually best brought out in the finger to-nose test any voluntary action on the part of the patient may throw not only the particular part in action but also the entire body The disturbance of speech dysarthric in nature is probably produced in the same way as the tremor While it is sometimes of a scanning nature it may simulate the speech of general paresis Nystagmus which may be lateral vertical or rotary or all three is usually due to a patch of sclerosis in the medulla or pons

The vision may be disturbed in multiple sclerosis long before changes of the fields or eye grounds However with prolonged observation pallor of the disks especially of a bitemporal nature may be found Impairment of the fields, particularly central scotomas for color is often present and may occur in the absence of changes in the disks Ocular palsies are not as prominent as pallor of the disks and nystagmus The abdominal reflexes due to involvement of the pyramidal tracts disappear The symptoms of pseudobulbar palsy, especially the emotional disturbance and a general euphoric trend may be seen

In old cases orthopedic procedures may be indicated. Occupational therapy is helpful not only in strengthening weak muscles but also in aiding the patient to acquire skills which may be economically valuable and in building and maintaining morale.

## MULTIPLE SCLEROSIS

*Synonyms*.—Disseminated sclerosis. Insular sclerosis.

This is a chronic disease of the central nervous system although it may run an acute or subacute course. The cause of the disease is not known. Experimentally demyelination has been produced as an allergic response and possibly allergy plays some role in the causation. In a few instances the disease may be familial occurring in siblings or in both parents and children. It may follow after an acute infectious disease. Apparently in some cases it has been precipitated by pregnancy. Trauma produces a condition which simulates multiple sclerosis.

The age at onset is usually between twenty and forty years although cases do occur earlier and later in life. In cases occurring in childhood especially in more than one member of a family one is more likely to be dealing with a familial disease of the extrapyramidal system.

*Pathologically* the disease is distinguished by numerous sclerotic patches scattered through the central nervous system. These patches are characterized by a degeneration of the myelin sheaths and a preservation of the axis cylinders which, however, are affected later. The optic nerves are involved, usually in the nature of a retrobulbar neuritis. The irregularity and the number of the sclerotic patches frequently makes for peculiar and bizarre symptoms. The white matter of the central nervous system is much more affected than the gray. The pyramidal tracts due to their great length, are practically always involved by sclerotic patches.

*Symptoms*.—The onset of the disease, while usually insidious, may be abrupt. Sudden blindness, hemiplegia, crural paraplegia and an ocular palsy may come on quickly and clear up. The preservation of the axis cylinders accounts for the return of power. The history in the ordinary case is usually first of numbness, parasthesia and weakness in the lower extremities followed by ataxia and tremor in the upper extremities, ocular disturbance and involvement of speech. The ocular signs are dimness of vision, blindness, nystagmus or perhaps a palsy of an ocular nerve. The classical *triad of Charcot*, namely tremor, scanning speech and nystagmus was at one time considered the chief symptoms in multiple sclerosis but it occurs only as a late manifestation in about 25 per cent of cases. One should be extremely hesitant in diagnosing multiple sclerosis without the presence of pyramidal tract signs. While sensory disturbances may be present, one would expect to see such changes more often than they occur; signs of posterior column disturbance are most common. The type of sensory loss will depend upon the exact location of the sclerotic patch responsible for it. The tremor which is called an intention or action tremor is made worse by movement. While it is usually best brought out in the finger-to-nose test, any voluntary action on the part of the patient may throw not only the particular part in action but also the entire body. The disturbance of speech, dysarthric in nature, is probably produced in the same way as the tremor. While it is sometimes of a scanning nature it may simulate the speech of general paresis. Nystagmus, which may be lateral, vertical or rotary or *all three*, is *usually* due to a patch of sclerosis in the medulla or pons.

visual fibers may be involved and temporal lobe symptoms also brought about

*Occipital Lobe* — The chief localizing symptom here produced is homonymous hemianopsia in the contralateral visual fields. Irritation of the visual cortex or of the optic radiations may produce visual hallucinations which are crude and often ill-defined.

Implication of the *optic thalamus* produces disturbance or loss of all forms of sensation on the opposite side of the body accompanied by dysesthetic phenomena. For example if a piece of ice or a very hot test tube is placed on the hand of the affected side the patient cannot appreciate them as cold or hot but says that it produces a nasty disagreeable painful sensation. Deep pressure and scratching with a pin will often produce the same unpleasant sensation. While not pathognomonic of lesions of the optic thalamus such symptoms are extremely suggestive. Spontaneous disagreeable and painful sensations may occur on the contralateral side. If the *pulvinar* is involved hemianopsia on the opposite side may occur. Mild lesions of the thalamus may not produce the devastating signs mentioned.

Lesions of the *corpus striatum* produce various types of involuntary movements and rigidity. If the internal capsule is not involved by lesions of the optic thalamus and corpus striatum pyramidal tract signs will not be present on the opposite side.

Involvement of the anterior part of the *internal capsule* produces hemiplegia on the contralateral side. Monoplegia is rarely if ever produced by a lesion in this locality. Implication of the posterior part of the internal capsule produces sensory loss and hemianopsia on the opposite side.

*Corpora Quadrigemina* — This locality contains functions which are chiefly visual and auditory. The superior corpora quadrigemina have to do with vision and the inferior with hearing. In lesions of this area the pupils are often dilated and fixed. Paralysis of upward gaze (Parinaud's syndrome) and signs of ocular palsies especially of the third nerve are common. Extension of the lesion to the red nucleus and superior cerebellar peduncles produces tremor and ataxia. Tumors of the quadrigeminal plate by compressing the aqueduct are prone to give rise to internal hydrocephalus with accompanying signs of increased intracranial pressure.

*Pineal Body* — Lesions of this structure which are usually tumors produce in effect the same symptoms as those of the corpora quadrigemina. In addition to the signs enumerated above pubertas precox may occur.

*Cerebral Peduncle* (*Crus Cerebri*) — A lesion of the anterior portion of this structure produces one of the typical forms of crossed hemiplegia namely third nerve paralysis on the side of the lesion and the face arm and leg on the opposite side. This is Weber's syndrome. If in addition the dorsal part of the peduncle is involved tremor and ataxia occur in the opposite limbs. The tremor simulates to some degree that of paralysis agitans but usually is not decreased on voluntary effort. The ataxia and tremor in such a case are due to implication of the red nucleus. This symptom complex is referred to as Benedikt's syndrome.

*Pons* — The type of crossed paralysis found in lesions of the pons is for the fifth sixth and seventh nerves to be paralyzed on the side of the lesion and the extremities on the opposite side. The common type of paralysis is for the seventh nerve on the ipsolateral side of the body to be involved and the extremities on the contralateral side. This is Millard Gubler type of crossed paralysis. The sixth nerve may be implicated in a Millard Gubler paralysis. Gliomas of the pons may assume great size before definite symptoms are produced. Tumors of the pons do not usually cause choked disk.

*Medulla* — Alternating hemiplegia and cranial nerve paralysis may occur from lesions of the medulla. Lesions implicating both pyramidal tracts will produce symptoms of such involvement below the level of the lesion. Occlusion of the posterior inferior cerebellar artery results in softening in the dorso-lateral portion of the medulla with involvement of the descending root of the fifth nerve and the spinothalamic tract which causes a crossed sensory paralysis of the face on the side of the lesion and extremities and trunk on the opposite. The patient tends to fall to the side of the lesion due to involvement of the restiform body

disease of the frontal lobe Weakness of the contralateral side of the face may be the only physical sign detected but it must be interpreted with care inasmuch as many normal persons cannot move both sides of the face equally well In blinking the eye on the affected side of the face may close just a *little later than its fellow* Lesions at the base of the frontal lobe, especially tumors, may cause diminution or loss of smell and may also, by pressure on an optic nerve, produce primary optic atrophy on the side of the lesion and choked disk on the opposite side (Kennedy syndrome) Lesions of the lower part of the third left prefrontal gyrus in a right handed person will cause motor aphasia The attention is often difficult to obtain and hold Inattention to the sphincters leads to frequent soiling of the person

Lesions, especially tumors of the *corpus callosum*, are characterized chiefly by various mental symptoms due to interference with the association tracts In some cases these are limited to apathy and indifference while in others there is difficulty in concentrating personality changes, or a frank psychosis Memory is defective, speech difficult or impossible and apraxia a common symptom The mental symptoms are often mistaken for senile dementia or paresis Patients frequently do not respond to questioning and look blankly at the examiner Paralysis or weakness of *the extremities may* occur, but usually mean extension of the lesion into the motor parts Cranial nerve symptoms are not present

The upper part of the *motor cortex* (paracentral lobule) governs movement of the lower part that is the toes and foot of the opposite side of the body The lowest part of the left motor cortex is in close relation to Broca's area The center for the lower extremity is supplied by a branch of the anterior cerebral artery and the rest of the motor cortex by a branch from the middle cerebral artery An occlusion of the artery supplying the foot and leg centers may produce a monoplegia on the opposite side with the usual signs of pyramidal tract disease Involvement of the motor cortex will produce weakness and finally paralysis of the opposite side of the body and if the lesion is an irritative one, Jacksonian epilepsy or partial continuous epilepsy may be present on the weakened side A slowly progressive hemiplegia is quite characteristic of a new growth, a slow hemorrhage or thrombosis or cerebral abscess Early in the stage of a gradually growing lesion *segmental cerebral monoplegia* may occur Sensory loss does not occur in a lesion which is pre Rolandic Subcortical lesions produce a progressive hemiplegia and in some cases focal epilepsy Irritation of the motor cortex instead of causing frank Jacksonian epilepsy may produce twitching movements on the opposite side

In a right handed individual lesions of the *right temporal lobe* which is in the present state of knowledge a silent area are difficult to recognize and it is only after neighboring structures are involved that localizing signs can be detected Lesions of left temporal lobe (first and second convolutions) cause a sensory aphasia or word deafness with a jargon speech Lesions deep in the temporal lobe may involve the optic radiation causing thereby defects in the visual fields of the opposite side These defects in the early stages are of a quadrantic nature Later on hemianopsia is produced

Lesions involving the *uncinate region* are characterized by peculiar epileptiform fits The aura of the seizure is often a sensation of smell or taste and is frequently although *not always an unpleasant one* The patient then passes into a peculiar dreamy state and this is followed by tasting or chewing movements If the visual fibers have been implicated crude visual hallucinations may occur in these attacks which may end in a generalized fit

Implication of the *postcentral gyrus* and *parietal lobe* is characterized chiefly by loss of sense of position point discrimination and localization and a disturbance of stereognostic perception The other forms of sensation such as pain touch heat and cold are little if at all affected Implication of the *left supramarginal gyrus* may produce apraxia and of the *left angular gyrus* word and letter blindness (alexia) If a lesion of this area such as tumor grows forward motor symptoms may be produced if downward into the subcortical region the

all right,' 'oh pshaw,' and 'oh boy, oh boy.' Another patient could say nothing but his name, which he would repeat over and over in a sing-song voice. This man could also carry the tune of a song, due probably to an intact singing center (?). The ability to write may be and usually is preserved in motor aphasia, although the patient may have to learn to write with the left hand. The power of pantomime is also preserved in motor aphasia. In hysterical loss of speech the patient as a rule cannot say any words at all, and other evidence of hysteria will be present. Furthermore, during the second stage of etherization the hysteric with loss of speech will talk.

Involvement of Wernicke's zone or the posterior part of the first and second temporal convolutions on the left produces sensory aphasia, also called jargon aphasia and Wernicke's aphasia. Implication of this particular part of the cortex produces word deafness. The patient is unable to understand perfectly what is said to him, although his hearing is normal. The words are as strange to him as though they were part of a foreign language; he cannot obey commands. In a pronounced type of word deafness he will be unable to follow a simple request such as 'put your right hand on top of your head.' On the other hand, the word deafness may be so slight that the patient fails only when given a number of commands at *once*, as *for example*, 'walk over to the door, open it, take off your coat and shake hands with me.' He must not be shown what to do. He is often unable to name a common object such as a knife or handkerchief which is shown him, although he may be able to use the object perfectly well. *Because of his word deafness he is* unable to write from dictation or to appreciate mistakes in speaking which he makes. Unlike the motor aphasic who suffers from a paucity of words, the sensory aphasic has plenty of words which he uses in a jargon. Lesions in the word hearing center are frequently *complicated by cuts in the* visual fields, due to involvement of the optic radiation.

*In mixed aphasia, the defect involves both* the patient's ability to express himself and to comprehend what is said to him.

In amnesic aphasia, the patient loses the ability to recall the names of common objects (amnesia), although he can describe the object and recognize the correct name when it is furnished to him. This form of aphasia results from a disturbance in language formulation. The lesion in such cases probably involves the dominant hemisphere in the area of the posterior part of the angular gyrus and the posterior part of the third temporal convolution.

*Visual aphasia* (*word blindness—alexia*) is due to a lesion of the dominant angular gyrus and produces a condition in which the patient can see words, letters and symbols but cannot interpret them. Here again it is as though he were gazing at a page written *in a foreign language*. Visual aphasia may vary from slight interruption to a complete loss of ability to name letters and words. He cannot copy sentences. Defects of the visual fields and parietal lobe symptoms may occur on the opposite side if the lesion extends beyond the angular gyrus. Involvement of all functions which go to make up speech produces *global aphasia*.

*Apraxia* is the inability to perform simple purposeful movements with the extremities when those parts show no loss of power or sensation and no ataxia. Apraxia may be ideational, ideomotor or motor. In the first, the ideas necessary to carry out an act are inadequate, resulting in a nonsensical act. Such a patient may, if given a cigarette and a match, put the match in his mouth and strike the cigarette. This type usually occurs in diffuse cerebral disease. In the ideomotor type, the association pathways between the ideational and motor kinesthetic centers are interrupted. The patient may show amorphous movements, may use the wrong gesture or the wrong muscle group. This is seen in lesions of the corpus callosum and in those which sever connections between the pre- and post-central gyri and other essential parts of the brain. Motor apraxia is produced by a subtotal lesion in a motor area of any extremity, resulting in an awkward movement, whereas the patient

In addition, certain cranial nerves especially the ninth and tenth may be involved Horner s syndrome may occur from involvement of the descending sympathetic tract

*Cerebellum* —The usual lesion in this structure is a tumor The symptoms produced are ipsilateral and consist of asynergia hypotonia and weakness, which is not however, of pyramidal tract origin but is due to the decreased muscle tone Alteration in the finger-to-nose test, the Holmes rebound phenomenon, a widened base of support and nystagmus occur in cerebellar lesions The gait is ataxic and reeling is not affected by closure of the eyes and the patient has a tendency to deviate to the side of the involvement The reflexes are reduced or lost and asthenia may be so pronounced as to simulate paralysis Involvement of the cerebellar peduncles may also produce cerebellar symptoms

*Cerebellopontile Angle* —This is a common location for neoplasms and inflammatory reactions especially syphilis The common tumor is one growing from the sheath of the eighth nerve producing tinnitus deafness and rarely dizziness Other cranial nerves especially the fifth and seventh may be implicated When the fifth is involved, symptoms simulating trigeminal neuralgia may occur but are differentiated by the sensory loss on the affected side The seventh nerve may be paralyzed but irritation of it may produce facial hemispasm or fits of twitching comparable to Jacksonian epilepsy Cerebellar symptoms and signs of increased intracranial pressure then ensue

*Pituitary Gland (Hypophysis)* —The gland may be the seat of atrophy or enlargement but the common lesion is a neoplasm which produces bitemporal hemianopsia This however may be preceded by minor visual field defects Choked disk in pituitary tumor is most uncommon but primary optic atrophy is frequently seen due to direct pressure on the chiasm Frohlich s syndrome may occur Pituitary basophilism has been described by Cushing its symptoms are adiposity involving the face neck and trunk amenorrhea and hypertrichosis in females hypertension hyperglycemia and bluish striæ in the skin Softening of the bones of the skeleton is a rare finding The syndrome occurs most frequently in young adults Roentgen ray evidence of involvement of the sella may be found

## APHASIA

Stewart defines aphasia as impairment or loss of speech due to the loss of memory for those signs vocal or written by means of which we exchange ideas with our fellow men The cortical centers which have to do with speech are on the left side of the brain in a right handed individual and on the right side in a left handed individual There are three important cortical areas concerned with speech namely the lower part of the third left prefrontal, which is the area for motor speech or Broca s area, the posterior part of the first and second temporal convolutions which has to do with word hearing and sensory speech and is sometimes called Wernicke s zone and the angular gyrus in which are stored images for words letters figures and signs Exact and precise localization of important functions in the cortex is denied by some especially Marie Aphasia is usually classified on the basis of the predominant defect as *(a)* motor or expressive *(b)* sensory or receptive *(c)* mixed and *(d)* amnesic Pure types of aphasia are very rarely encountered

Motor aphasia is caused by a lesion of Broca s area Because of the proximity of the face tongue and hand centers to Broca s area lesions of the latter will often implicate cortical motor centers and produce segmental cerebral monoplegia In motor aphasia the patient has lost the power partially or completely to express himself in spoken words The extent of the aphasia will vary with the severity of the lesion He may have slight difficulty with speech or if the lesion is extensive speech may be entirely lost If the disturbance of speech is slight and mistakes are made the patient usually recognizes them While the patient may be speechless he is practically never wordless but has a recurring utterance which he will use either spontaneously or in reply to questions Expressions of some patients who have recurrent utterances are as follows

anyone any I know I know I know

the artery of cerebral apoplexy. The result *of occlusion of this vessel or of the middle* cerebral produces the commonest condition seen as the result of vascular injury, namely *hemiplegia*. The ordinary type of hemiplegia is more frequent in men, and usually occurs after the age of forty or forty-five years. If a stroke occurs before forty it is imperative that such disorders as syphilis, embolism, vascular anomalies, brain abscess, cerebral tumor and encephalitis be ruled out as the causative factor.

The usual location of hemorrhage or softening is in the region of the internal capsule. The size of a hemorrhage may vary greatly from a small lesion to a large one which may involve a great part of the cerebral *hemisphere and which may ultimately* rupture into the ventricles. If the patient dies shortly after a cerebral hemorrhage has occurred the lesion will have the appearance of freshly coagulated blood; later it goes through various color changes and a cyst or cavity remains. The apoplectic seizure may be initiated by injury, may come on as the result of severe muscle exertion such as the exertion of paroxysmal coughing as occurs in whooping cough, straining at stool during coitus, parturition or any severe muscular effort. Many cases of apoplexy *occur in patients with low blood* pressure. The *apoplectic seizure* may be preceded by certain premonitory symptoms such as numbness on the side of the body about to be paralyzed, headache, dizziness, *vomiting, convulsions or confusion.* Many patients have been conscious for months or years that they are the victims of high blood pressure and kidney disease, but on the other hand others feel in normal health. Physical overexertion and anxiety may apparently produce a cerebral attack in middle age and in supposedly healthy individuals.

*Symptoms.—Immediately after* a vessel has been damaged the patient usually becomes comatose, although occasionally consciousness is completely retained. In a patient who has a cerebral hemorrhage the onset is more rapid and the coma deeper than in a patient with thrombosis. The case of cerebral hemorrhage is very ill from the start. The breathing is stertorous and at times of the Cheyne-Stokes type. The face is flushed, the pupils may be small, normal *or dilated, and are frequently* unequal. The corneal reflexes are abolished, the individual is shocked, all the extremities are likely to be flaccid, the deep reflexes especially on the side of the paralysis may be absent. The plantar reflex will practically always be of the extensor type on the paralyzed side, even though the deep reflexes are lost. Despite the fact that all the extremities are flaccid and drop helplessly to the side when they are lifted from the bed, those on the paralyzed side are much more toneless than those on the other. In the stage of shock *swallowing is impossible and the* control of the sphincters is lost. Some degree of fever occurs soon after the onset. *Steadily rising temperature* is a bad prognostic sign. Later on the presence of fever may be due to pneumonia. If the urine is examined it will frequently be found to show evidence of nephritis or of diabetes; however sugar may be found in the urine as the result of a cerebral lesion alone. If the hemorrhage ruptures into the ventricles the patient becomes extremely ill and signs of meningeal irritation occur. The picture of decerebrate rigidity may present itself in patients with hemorrhage into the ventricles. Pyramidal tract signs are bilateral. Pronounced respiratory *difficulties ensue, the pulse slow at* first becomes rapid, the temperature may become subnormal or high, and the patient dies, as a rule, within two to seven days. Lumbar puncture reveals a bloody fluid.

*The onset in cerebral thrombosis is usually* not so abrupt, premonitory symptoms are more commonly seen, the patient is not so severely shocked, stupor if present is not as deep as in hemorrhage. Furthermore, partial paralysis may exist a number of hours, even a week or more before becoming complete. This is especially so when the *artery in the Sylvian fissure is involved.* Cerebral embolism which usually results from heart disease, particularly subacute endocarditis, may resemble thrombosis, but the onset is usually sudden. The diagnosis is based on the heart findings and in some cases the finding of a positive blood culture. The retinal vessels will usually show arteriosclerosis and rarely the optic nerves show signs of neuritis or of choking.

formerly was able to carry out fine movements with the same part.

In the differential diagnosis aphasia of the sensory type and agnosia must be ruled out as well as extrapyramidal movements such as are seen in chorea and athetosis.

*Agnosia* may be defined as a loss of the ability to recognize objects in the absence of any impairment of the perceptive functions of the sense organs. In auditory agnosia (psychic deafness) the patient is unable to identify auditory stimuli; for example, with his eyes closed he cannot identify a dog by its bark or a bell by its tinkle. This is due to a disturbance in the association fibers connecting the auditory sensory center in the temporal lobe with the conceptual center in the frontal lobe. Often there is an accompanying sensory aphasia. In visual agnosia (psychic blindness), the patient loses the understanding of the significance of an object. For example, he may describe a knife accurately but can not recognize what it is. This occurs in lesions involving the convexity of the occipital lobe. Tactile agnosia or astereognosis, as previously noted, occurs with lesions of the postcentral gyrus.

The testamentory capacity of patients suffering from various forms of aphasia is often brought up. The uncomplicated cases of motor aphasia will usually have testamentory capacity and a disposing mind. By talking with such an individual his will and desire can be appreciated. On the other hand, it is impossible to communicate sufficiently with the patient suffering from sensory aphasia to know what disposition of his property he might wish to make, and there is a question if wills made by such patients should be allowed to stand.

## DISORDERS OF ARTICULATION

Articulation has nothing to do with cortical functions but is a function of the bulb and the peripheral mechanisms. A patient with advanced bulbar palsy or pseudobulbar palsy may be unable to put forth a single word, yet he is not speechless. Difficulty in articulation is spoken of as dysarthria and is common for example in pseudobulbar palsy. If the disturbance of articulation is advanced it may render the patient unable to say a word or make a sound. This is called *anarthria*. Involvement of articulation may be due to lesions of the cranial nerves or their nuclei which have to do with speech, to supranuclear involvement as in pseudobulbar palsy, or to incoordination of the muscles of the lips, tongue, palate, pharynx and larynx. A slurred type of speech is common in alcoholism and paresis. Sometimes the speech of multiple sclerosis may be slurred and simulate that of general paresis. Tremor or involuntary movements affecting the movements of articulation may produce *dysarthria*. In paralysis agitans the voice is monotonous and often has a festinating character. The most common type of speech disturbance is stammering. This is most frequently found in males who are usually above the average intelligence and are frequently of a psychasthenic makeup. *Stammering* is an incoordination between the vocal and oral mechanisms of speech, and the stammerer frequently sticks on an initial consonant or syllable. Stammering is usually increased by excitement and for the most part disappears when the stammerer sings. Most stammerers acquire certain tricks which aid them to overcome their speech defect; they most commonly make certain grimaces or quick tic-like movements of the body or the extremities. These are often not unlike the tic movements which the psychasthenic shows. When stammering appears it should be treated by exercise and speech training. While the child may grow out of it, he will certainly do so more quickly if he has the proper training.

*Hysteria may produce certain disturbances* in articulation in which the voice may be entirely lost or the patient can speak only in a whisper. *Hysterical mutism* may or may not be accompanied by paralysis, and the patient can always write.

## DISEASES OF THE BLOOD VESSELS OF THE BRAIN

*Etiology.*—The commonest condition affecting the blood vessels of the brain is arteriosclerosis, which may be part of the generalized disease, or it may be limited to the vessels of the brain. Vessels which are diseased by arteriosclerosis may give rise to a cerebral hemorrhage; they may thrombose, causing secondary softening beyond the point of the lesion; or the cerebral vessels may be the site of aneurysms. On the other hand, a cerebral vessel may be plugged up with an embolus, or it may be implicated by aneurysm produced by the lodging of microorganisms in its wall with subsequent weakness and dilatation. Any vessel of the brain may be the site of vascular insult, but the lenticulo-striate artery is so *frequently involved that it has been called*

out the production of symptoms referable to the entire cortex supplied by the artery

In considering the *differential diagnosis* of apoplexy it is necessary to consider all of the causes which may produce stupor or coma Of 200 cases with coma 83 had skull fractures 53 apoplexy, 12 uremia, 10 lobar pneumonia, 8 meningitis and 6 diabetic coma In the rest it was due to scattered causes In other studies cerebral hemorrhage has been shown to be the most common medical cause of coma (excluding trauma and alcoholism) There is no doubt of the frequency with which *uremia* is overdiagnosed A great tendency exists to label a patient unconscious, with paralysis of one side and with albumin and casts in the urine as a uremic hemiplegic As a matter of fact such cases are most often due to cerebral hemorrhage *Injuries to the head*, especially those persons who suffer cerebral hemorrhage without fracture can usually be differentiated by the history *Diabetic coma* can be determined by the analysis of the blood and urine but it must be remembered that cerebral lesions may produce glycosuria The diagnosis between *apoplexy* and *postepileptic stupor* can be made in some cases by the record and by the absence of paralysis although the plantar reflex may be of the extensor type due to cortical exhaustion after a fit Further more scars may be found upon the face and tongue of the epileptic and he may have the facies peculiar to those people In some cases an exhaustion paralysis occurs after a series of epileptic fits especially if they are unilateral On the other hand an epileptic may rupture a cerebral vessel (either intra or extracerebral) during a spasm and a hemiplegia will result *Hysterical hemiplegia* is differentiated by the absence of abnormal reflexes loss of sensation often exists on the paralyzed side hearing and vision may be affected on the paralyzed side other symptoms suggestive of hysteria may be detected Alcoholic coma can be diagnosed by the history of the individual the usual absence of pathologic reflexes and of paralysis and the tendency toward delirium and restlessness Because of the ease with which such *drugs* as the barbiturates are obtained patients are not infrequently seen in coma produced by the overuse of those drugs In the absence of the history therefore the diagnosis is difficult Hematoporphyrin in the urine may give an important clue in patients comatose from such drugs as veronal *Hyperinsulinism* may produce coma and be accompanied by bilateral pyramidal tract signs (*See* Chapter 15) Spontaneous *subarachnoid hemorrhage* may induce stupor and because of the presence of blood in the spinal fluid may be confused with cerebral hemorrhage with rupture into the ventricles However in the latter the patient is always much sicker than in the former is more deeply stuporous and will show more extensive paralysis A patient suffering from a *brain tumor* may have a hemiplegia of apoplectic suddenness due to hemorrhage into the tumor The possibility of brain tumor is often not thought of in such cases, but examination of the eye grounds and estimation of the spinal pressure will help in the diagnosis

*Treatment* —The most important thing under this heading is prophylaxis For this the reader is referred to the article on arteriosclerosis In the acute attack the patient must necessarily be put to bed the head should be slightly elevated An olive oil or a simple enema should be given immediately

Owing to the frequency with which hypostatic pneumonia develops penicillin or some other antibiotic should be administered and the patient should be kept off his back and on the paralyzed side as much as possible The position should be changed frequently An air mattress or water mattress should be used to prevent the occurrence of trophic sores An ice bag to the head sedatives for great restlessness and absolute cleanliness of the skin are important considerations in the treatment If swallowing is either impaired or impossible great care should be used in giving the patient food or liquids by mouth For the first two or three days it is better to give liquids by rectum or with a nasal tube rather than to run the risk of having the patient aspirate it into the lungs The treatment is chiefly symptomatic In cases of cerebral thrombosis immediate stellate block ipsilateral to the lesion has been advocated to relieve cerebral vasospasm

It is our experience that those cases of hemiplegia associated with *choked disks* are usually due to cerebral neoplasm A conjugate deviation of the eyes, usually toward the side of the cerebral lesion may be seen Most patients with cerebral hemorrhage die A patient with cerebral thrombosis has a much better *chance to survive If he does he will then present the picture* of a hemiplegia, that is, paralysis or weakness of one side of the body with contractures and the signs of pyramidal tract disease

*Sensation* is not affected in the ordinary case of hemiplegia, unless the thalamus or the posterior limb of the capsule is involved *pain on the paralyzed side is due to thalamic* irritation or to joint disease which is especially likely to occur in the shoulder Early in the history of the case the patient s *speech* will be dysarthric or even absent If the dominant cortex has been involved speech may be greatly affected and either motor or *sensory aphasia or both exist*

Many patients suffering from cerebral vascular disease die within a few weeks others recover enough power on the affected side to permit their getting up and around The lower extremity recovers more power than the upper and the proximal segments of the *upper extremity regain more strength* than the distal ones In walking the hemiplegic patient swings the entire lower extremity on the affected side from the hip the knee is *held rigidly and the toe is scraped* along the floor The arm is slightly abducted the elbow usually flexed to a right angle the hand *is pronated* and bent and the fingers are flexed Often the hand on the paralyzed side is carried across the lower part of the abdomen although occasionally it is held in extension at the side *Contractures* will occur unless attention is directed to their prevention If the paralysis remains a *flaccid one*, the patient will not as a rule recover function Atrophy may occur on the paralyzed side and may be due to inactivity and to ankylosis *Electrical reactions* remain normal In a lesion of the thalamus or posterior limb of the capsule all forms of sensation may be seriously affected hemianopsia may occur and the paralyzed or weak limbs may be the site of disagreeable sensations or actual pain Pain on the paralyzed side may be produced, especially *in a lesion of the thalamus, by testing* the patient for sensation, thus, the application of a piece of ice, an extremely hot test tube or deep pressure on the paralyzed side or scratching it with a pin may provoke an abnormal response, which has *been referred to as dysesthesia* While this is characteristic of disease of the thalamus it may occur from irritation, to the sensory pathways in other parts of the central nervous system

*Trophic disorders* may occur on the paralyzed side in the joints, skin or nails and muscular atrophy may be due to trophic disturbances or to joint disease Occasionally one sees hemiplegia which, after a few hours' duration, clears up suddenly This may be due to a spasm of the cerebral vessel Hemiplegia of short duration is a common happening in general paresis

If the carotid artery is thrombosed before *it gives off the ophthalmic artery, there is* blindness on the side of the lesion and a hemiplegia on the opposite side

Even in the most favorable case a certain amount of reduction in the *mental faculties* of the individual ensues If the lesion has been a large one and especially if bilateral changes caused by arteriosclerosis are present mental changes may occur varying from acute psychosis to a severe dementia Vascular disease involving the pons or *medulla may occur These usually produce* a crossed paralysis Hemorrhage into the pons sometimes occurs in brain abscess or tumor or in other conditions producing increased pressure and frequently causes sudden death

Occlusion of the branch of the anterior cerebral artery supplying the foot and leg center will cause a *monoplegia* of the lower extremity on the opposite side to the lesion Occlusion of the Sylvian artery is not an infrequent occurrence and if the *left Sylvian* artery be involved a devastating group of symptoms ensues because of implication of the special centers located on the left side of the brain Any one of the branches of the Sylvian artery may become affected without involvement of the entire artery motor aphasia sensory aphasia alexia parietal lobe symptoms or paralysis may ensue with

out the production of symptoms referable to the entire cortex supplied by the artery

In considering the *differential diagnosis* of apoplexy it is necessary to consider all of the causes which may produce stupor or coma *Of 200 cases with coma 83 had skull* fractures 53 apoplexy, 12 uremia 10 lobar pneumonia, 8 meningitis and 6 diabetic coma In the rest it was due to scattered causes In other studies cerebral hemorrhage has been shown to be the most common medical cause of coma (excluding trauma and alcoholism) There is no doubt of the frequency with which *uremia* is overdiagnosed A great tendency exists to label a patient unconscious with paralysis of one side and with albumin and casts in the urine as a uremic hemiplegic As a matter of fact such cases are most often due to cerebral hemorrhage *Injuries to the head* especially those persons who suffer cerebral hemorrhage without fracture can usually be differentiated by the history *Diabetic coma* can be determined by the analysis of the blood and urine but it must be remembered that cerebral lesions may produce glycosuria The diagnosis between *apoplexy* and *postepileptic stupor* can be made in some cases by the record and by the absence of paralysis although the plantar reflex may be of the extensor type due to cortical exhaustion after a fit Furthermore scars may be found upon the face and tongue of the epileptic and he may have the facies peculiar to those people In some cases an exhaustion paralysis occurs after a series of epileptic fits especially if they are unilateral On the other hand an epileptic may rupture a cerebral vessel (either intra or extracerebral) during a spasm and a hemiplegia will result *Hysterical hemiplegia* is differentiated by the absence of abnormal reflexes loss of sensation often exists on the paralyzed side hearing and vision may be affected on the paralyzed side other symptoms suggestive of hysteria may be detected Alcoholic coma can be diagnosed by the history of the individual the usual absence of pathologic reflexes and of paralysis and the tendency toward delirium and restlessness Because of the ease with which such *drugs* as the barbiturates are obtained patients are not infrequently seen in coma produced by the overuse of those drugs In the absence of the history therefore the diagnosis is difficult Hematoporphyrin in the urine may give an important clue in patients comatose from such drugs as veronal *Hyperinsulinism may produce* coma and be accompanied by bilateral pyramidal tract signs (*See* Chapter 15) Spontaneous *subarachnoid hemorrhage* may induce stupor and because of the presence of blood in the spinal fluid, may be confused with cerebral hemorrhage with rupture into the ventricles However in the latter, the patient is always much sicker than in the former is more deeply stuporous and will show more extensive paralysis A patient suffering from a *brain tumor* may have a hemiplegia of apoplectic suddenness due to hemorrhage into the tumor The possibility of brain tumor is often not thought of in such cases but examination of the eyegrounds and estimation of the spinal pressure will help in the diagnosis

*Treatment* —The most important thing under this heading is prophylaxis For this the reader is referred to the article on arteriosclerosis In the acute attack the patient must necessarily be put to bed the head should be slightly elevated An olive oil or a simple enema should be given immediately

Owing to the frequency with which hypostatic pneumonia develops penicillin or some other antibiotic should be administered and the patient should be kept off his back and on the paralyzed side as much as possible The position should be changed frequently An air mattress or water mattress should be used to prevent the occurrence of trophic sores An ice bag to the head sedatives for great restlessness and absolute cleanliness of the skin are important considerations in the treatment If swallowing is either impaired or impossible great care should be used in giving the patient food or liquids by mouth For the first two or three days it is better to give liquids by rectum or with a nasal tube rather than to run the risk of having the patient aspirate it into the lungs The treatment is chiefly symptomatic In cases of cerebral thrombosis immediate stellate block ipsilateral to the lesion has been advocated to relieve cerebral vasospasm

The block must be repeated frequently and is of little or no value if the hemiplegia has existed for more than a few hours While encouraging results have been reported by a few investigators our own experience has not been so favorable Stellate block is contraindicated in cerebral hemorrhage At present this method of treatment should still be considered as being in the experimental stage

Since the cerebrovascular accident frequently occurs as a manifestation of systemic circulatory failure, therapy directed toward improving the general circulation should be instituted

If the patient survives to become a hemiplegic the paralyzed limb should be given massage and passive movement These forms of physiotherapy should be employed early in the case certainly by the end of the first week, otherwise the tendency toward contractures and joint changes will be great Electricity is chiefly of psychotherapeutic value Rarely orthopedic operations, may be employed Aphasia if present, may improve spontaneously but it is usually necessary to attempt to reeducate the individual

## SPONTANEOUS SUBARACHNOID HEMORRHAGE

Spontaneous subarachnoid hemorrhage is not uncommon At the Philadelphia General Hospital it was found in nearly 2 per cent of all brain autopsies Almost invariably it results from the rupture of a miliary or berry aneurysm of the circle of Willis These aneurysms are due to a congenital defect in the media and are invariably located at the point where the artery gives off branches In a series of 45 cases reported by Wilson, Rupp and Bartle 17 occurred in the internal carotid artery 16 on the anterior communicating, 5 on the middle cerebral, 2 each on the anterior cerebral and basilar arteries and one each on the posterior cerebral posterior inferior cerebellar, and superior cerebellar arteries respectively Trauma syphilis and arteriosclerosis are not important as etiologic factors The exact cause of the rupture of these aneurysms is not known but a close parallelism exists between these cases and those showing a primary intracerebral hemorrhage in respect to age incidence elevation of blood pressure and the presence of concomitant cardiac vascular disease

*Symptoms*—Spontaneous subarachnoid hemorrhage may occur at any age The average age in the cases reported by us was forty four years The onset is usually abrupt but may be insidious In some cases the hemorrhage may follow severe activity or emotional excitement while in many cases there is no discernible precipitating cause The patient may first complain of severe headache and dizziness and fall to the ground Coma psychic disturbances such as confusion excitement and hallucinations and convulsions may be present Nuchal rigidity and Kernig s signs are almost always present The pupils may be unequal extra ocular muscle palsies and other evidence of cranial nerve dysfunction may be noted Hemiplegia or hemiparesis not infrequently are found The tendon reflexes vary greatly they may be increased or in some cases decreased Babinski s sign is sometimes seen on one side or both If the patient is not completely stuporous he will probably complain of a severe headache associated perhaps with vomiting The eye grounds may reveal swelling and retinal hemorrhages may occur The pulse and respiration may be slow or rapid depending upon the intracranial pressure and shock and a moderate rise of temperature frequently exists Glycosuria and hyperglycemia have been found at times and may lead to an erroneous diagnosis of diabetic coma At first the spinal fluid is bloody and the pressure increased later the fluid becomes xanthochromic

*Diagnosis*—The diagnosis of spontaneous subarachnoid hemorrhage should be considered as a possibility in any patient in stupor The history of sudden onset the signs of meningeal irritation and the presence of blood in the spinal fluid suggest the diagnosis Recovery occurs in about 50 per cent of the cases but later there may be another rupture which may prove fatal The aneurysm may frequently be visualized by angiography

*Treatment* —In the acute stage therapy is largely symptomatic The general circulatory status should not be neglected and any therapy which might increase its efficiency should be instituted If the patient is restless, sedatives such as paraldehyde by rectum or sodium phenobarbital hypodermically should be administered Morphine is contraindicated An ice bag to the head may be comforting if headache is severe Repeated spinal punctures are not recommended unless headache is quite severe, persistent and cannot be alleviated by other means since fresh bleeding may cause death Occasionally other methods of reducing increased intracranial pressure such as magnesium sulfate enemas and hypertonic intravenous solutions may be used If the patient survives the acute manifestations surgical procedures to prevent further bleeding may be justified In some cases the aneurysm may be clipped intracranially in others, tying the carotid artery on the side of the aneurysm may be considered These procedures are not without danger and therapy must always be individualized

## SINUS THROMBOSIS

The various sinuses of the brain may be occluded either as the result of infection or as a terminal state in such conditions as tuberculosis paresis cardiac disease, pregnancy and after any long standing debilitating disease The type of sinus thrombosis produced by infections may be complicated by meningitis or brain abscess and also by extradural collections of pus The sinus most frequently involved is the lateral sinus which is affected secondarily to disease of the ear The cavernous sinus may be implicated by infections about the face especially those on the upper lip and about the tip of the nose Fortunately the incidence of these serious complications has been greatly reduced since the advent of the antibiotics The common cause of thrombosis of the superior longitudinal sinus is long standing illness

The sinus thrombosis may be localized or may be very extensive especially in the type produced by infections The walls of the sinus may be eroded and death occur suddenly from hemorrhage Cerebral hemorrhage may occur, especially when the superior longitudinal sinus is thrombosed because the brain cannot properly be drained of blood, and hyperemia and bleeding ensue

*Symptoms* —Symptoms of occlusion of the superior longitudinal sinus are as follows signs of increased intracranial pressure are present often accompanied by paralysis which is due, as a rule, to cortical bleeding Generalized or Jacksonian convulsions may occur Signs of meningitis may be present

Thrombosis of the cavernous sinus produces swelling of the eyelids on the affected side swelling at the root of the nose exophthalmos and as a rule paralysis of all the ocular nerves on that side Visual disturbances are common and there may be choking of the disk Implication of the ophthalmic division of the fifth nerve may cause pain in its distribution The opposite cavernous sinus may be involved secondarily Thrombosis of the sigmoid or the lateral sinus may produce a swelling at the upper part of the jugular vein which may be palpated Swelling in the mastoid region signs of meningitis and occasionally paralysis of the lower cranial nerves on the affected side may be discovered A modification of the Queckenstedt test the Tobey Ayer test may produce valuable evidence in lateral sinus thrombosis In this test the pressure on the jugular vein on the normal side causes a rise in the spinal pressure whereas if the jugular vein is thrombosed there will be no rise Occasionally in cases of infections of the ear the so-called *Gradenigo syndrome* may be present The chief symptom of this is a paralysis of the sixth nerve on the side of the lesion and occasionally symptoms indicative of implication of the sensory part of the fifth nerve These symptoms may be due to an aseptic meningitis which may quickly disappear there is however always cause for alarm in the possibility of meningitis or abscess Petrositis is a complication of middle ear disease The acute symptoms are signs of sepsis periauricular pain interference with movements of the lower jaw, these may be followed by chronic suppuration of the petrous tip with pain in and around the eye and *Gradenigo s syndrome* Vertigo and

The block must be repeated frequently and is of little or no value if the hemiplegia has existed for more than a few hours. While encouraging results have been reported by a few investigators, our own experience has not been so favorable. Stellate block is contraindicated in cerebral hemorrhage. At present, this method of treatment should still be considered as being in the experimental stage.

Since the cerebrovascular accident frequently occurs as a manifestation of systemic circulatory failure, therapy directed toward improving the *general circulation* should be instituted.

If the patient survives to become a hemiplegic, the paralyzed limb should be given massage and passive movement. These forms of physiotherapy should be employed early in the case, certainly by the end of the first week; otherwise the tendency toward contractures and joint changes will be great. Electricity is chiefly of psychotherapeutic value. Rarely orthopedic operations may be employed. Aphasia, if present, may improve spontaneously, but it is usually necessary to attempt to re-educate the individual.

## SPONTANEOUS SUBARACHNOID HEMORRHAGE

Spontaneous subarachnoid hemorrhage is not uncommon. At the Philadelphia General Hospital it was found in nearly 2 per cent of all brain autopsies. Almost invariably it results from the rupture of a miliary or berry aneurysm of the circle of Willis. These aneurysms are due to a congenital defect in the media and are invariably located at the point where the artery gives off branches. In a series of 45 cases reported by Wilson, Rupp and Barthe 17 occurred in the internal carotid artery, 16 on the anterior communicating, 5 on the middle cerebral, 2 each on the anterior cerebral and basilar arteries, and one each on the posterior cerebral, posterior inferior cerebellar, and superior cerebellar arteries, respectively. Trauma, syphilis and arteriosclerosis are not important as etiologic factors. The exact cause of the rupture of these aneurysms is not known, but a close parallelism exists between these cases and those showing a primary intracerebral hemorrhage in respect to age incidence, elevation of blood pressure and the presence of concomitant cardiac vascular disease.

*Symptoms.*—Spontaneous subarachnoid hemorrhage may occur at any age. The average age in the cases reported by us was forty-four years. The onset is usually abrupt but may be insidious. In some cases the hemorrhage may follow severe activity or emotional excitement, while in many cases there is no discernible precipitating cause. The patient may first complain of severe headache and dizziness and fall to the ground. Coma, psychic disturbances such as confusion, excitement and hallucinations, and convulsions may be present. Nuchal rigidity and Kernig's signs are almost always present. The pupils may be unequal; extra-ocular muscle palsies and other evidence of cranial nerve dysfunction may be noted. Hemiplegia or hemiparesis not infrequently are found. The tendon reflexes vary greatly; they may be increased or in some cases decreased. Babinski's sign is sometimes seen on one side or both. If the patient is not completely stuporous he will probably complain of a severe headache, associated perhaps with vomiting. The eye grounds may reveal swelling, and retinal hemorrhage may occur. The pulse and respiration may be slow or rapid, depending upon the intracranial pressure and shock, and a moderate rise of temperature frequently exists. Glycosuria and hyperglycemia have been found at times and may lead to an erroneous diagnosis of diabetic coma. At first the spinal fluid is bloody and the pressure increased; later the fluid becomes xanthochromic.

*Diagnosis.*—The diagnosis of spontaneous subarachnoid hemorrhage should be considered as a possibility in any patient in stupor. The history of sudden onset, the signs of meningeal irritation and the presence of blood in the spinal fluid suggest the diagnosis. Recovery occurs in about 50 per cent of the cases, but later there may be another rupture which may prove fatal. The aneurysm may frequently be visualized by angiography.

plasm which often spreads through the subarachnoid space and occurs most frequently in the mid line of the cerebellum in children This type of tumor can be held in check for a time by radiation An oligodendroglioma is a slowly growing tumor which usually arises from the cortex and often becomes calcified It is most common in the early thirties of life Gliomata are usually single and are frequently the site of degeneration and hemorrhage

*Endothelioma* (fibroblastoma, meningioma) is a relatively benign tumor which usually arises from the arachnoid villi and may occasionally become calcified when it is called a psammoma It occurs most commonly in the middle years of life A large majority are found in the anterior two thirds of the skull They may be found close to the falx in the midline in the Sylvian fissure and on the sphenoidal ridge in the olfactory groove tuberculum sellae or parasellar regions Less commonly they are found on the petrous ridge or in the posterior fossa Fibroblastomata may produce hyperostosis of the cranium or occasionally thinning or even erosion of the bone

*Acoustic fibromata* or *neuromas* are benign circumscribed growths growing from the dural sheath of the eighth nerve They may occur as bilateral angle tumors

*Tuberculomas* may be single or multiple usually the latter and are often secondary to tuberculosis elsewhere in the body although sometimes no other tuberculous focus can be detected They usually have a connective tissue capsule and frequently central caseation occurs Rarely the tubercle becomes calcified and does not produce symptoms A diffuse tuberculous meningitis is often a common end result of a tuberculoma They are found in adults as well as in children grow slowly and occur thoughout the cortex cerebellum and brain stem

*Gummata* are rare and usually multiple

*Adenomata* occur in the pituitary gland and are extremely important in relation to acromegaly and Frohlich s syndrome

*Sarcomata* are either primary or secondary and single or multiple They usually grow from the meninges into the brain and may be encapsulated or invasive They may be secondary from sarcomata elsewhere in the body *Other tumors* such as cholesteatoma dermoid cysts and teratomata are rare

*Carcinomas* are always secondary grow rapidly are usually multiple and quite vascular The presence of carcinoma elsewhere in the body should always be ruled out before operating upon a brain tumor suspect This is especially important when a person is above the age of forty years as sometimes the intracranial manifestations may be the earliest evidence of carcinoma

*Angiomata* arise from the blood vessels of the meninges and may be associated with birthmarks on the scalp or face Angiomata are especially likely to be seen in the precentral region *Lindau s disease* consists of angioma of the brain and angiomatosis of the retina

The *cause* of brain tumors is unknown Their relation to trauma is a most important one especially from a medico-legal aspect Endotheliomata undoubtedly sometimes follow trauma The general symptoms of a brain tumor may be abruptly brought on by head injury but it is extremely doubtful if the tumor itself can be produced by trauma

*Symptoms* —The expressions of brain tumors are both general and focal The most constant symptom is headache and while it may be occasionally absent it practically always occurs sometime in the history of the case Severe *headache* especially if associated with dizziness and vomiting should always arouse suspicion of a cerebral neoplasm The headache is usually generalized but may be located either in the occipital or frontal regions when it may be associated with local tenderness Headache is due to stretching of the dural blood vessels *Choked disk* or papilledema is a frequent sign of brain tumor but may not occur until late in the course The presence of choked disk indicates a brain tumor in at least 90 per cent of cases and the burden of the proof is on him who propounds another diagnosis Choked disk is most frequently seen with tumors which block the ventriculo subarachnoid pathways and cause increased ventricular pressure it is an extremely common sign in tumors in the posterior fossa Papilledema is usually bilateral but frequently is more pronounced on one side A

nystagmus may be seen in the chronic form Paralysis of the seventh nerve may take place, and other cranial nerves may be implicated The condition may subside or meningitis or brain abscess follow

Signs of meningitis make it imperative to perform a lumbar puncture Only enough fluid should be withdrawn, however to determine the color and transparency to count the cells and make a smear for organisms The fluid may contain an excess of cells and no organisms

The outlook in cases of sinus thrombosis is serious Penicillin sulfa compounds and other antibiotics should be given immediately Septic foci must be drained surgically Ligation of the facial vein may be employed as a prophylaxis against the involvement of the cavernous sinus

## CEREBRAL ANEURYSM

Cerebral aneurysms are most frequently congenital in origin and are due to defects in the development of the cerebral blood vessels Most common are the miliary type which are found at the base of the brain at the points of bifurcation of branches of the arteries composing the circle of Willis Occasionally congenital arterio-venous aneurysms are present Rarely the aneurysms are of infectious (embolic) origin or are the results of syphilitic or arteriosclerotic involvement of the vessels The arteries at the base of the brain are more frequently involved and aneurysms are likely to be multiple They are usually small but occasionally attain a fairly large size before rupturing The parts of the brain in the immediate vicinity of a cerebral anerurysm may undergo a pressure atrophy Trauma may play a role in the production of a cerebral aneurysm and it is certain that sufficient trauma can cause the rupture of a cerebral aneurysm already present

Before the rupture occurs the aneurysm may produce *symptoms* such as headache often referred to the side on which it exists vomiting and dizziness A murmur may be heard over the skull This may be localized or heard over a widespread area A murmur may also be detected over the skull in rickets, hydrocephalus hyperthyroidism and occasionally over a neoplasm General signs of increased pressure are rarely found If an aneurysm ruptures, which it may do either spontaneously or as a result of trauma or severe muscular effort a massive hemorrhage may occur Slow bleeding may take place into the subarachnoid space If the aneurysm is near the ventricular system and ruptures into it signs of intraventricular hemorrhage will exist Aneurysms of the large vessels of the brain other than those at the base will produce symptoms referable to the parts of the brain involved The optic and olfactory nerves may be compressed by an aneurysm of the anterior cerebral artery and an aneurysm of the internal carotid may affect the ocular nerves in addition to the optic and olfactory and even occasionally the fifth If the aneurysm perforates into the cavernous sinus pulsating exophthalmos may occur

The *diagnosis* of cerebral aneurysm is sometimes difficult but if suspected confirmation may usually be obtained by angiography In a patient suffering from subarachnoid bleeding non traumatic in origin it is fair to assume the hemorrhage has been due to the rupture of a small aneurysm The treatment in general is that of subarachnoid hemorrhage and of cerebral hemorrhage Surgical intervention may be helpful

## *BRAIN TUMORS*

Brain tumors comprise from 1 to 2 per cent of all neurologic disorders The tumor may be primary in the brain and its appendages or metastatic from a neoplasm elsewhere in the body

*Pathology* —The most common brain tumors are *gliomas* which comprise from 40 to 50 per cent of all intracranial neoplasms Various types of glioma are to be distinguished Glioblastoma multiforme (gliosarcoma—spongioblastoma multiforme) is usually seen in middle life occurs in the hemispheres is malignant and attains large size An astrocytoma is more benign has a tendency to become cystic and may involve the cerebrum or cerebellum It occurs usually in children or in young adults A medulloblastoma is a rapidly growing neo-

plasm which often spreads through the subarachnoid space and occurs most frequently in the mid line of the cerebellum in children This type of tumor can be held in check for a time by *radiation* An *oligodendroglioma* is a slowly growing tumor which usually arises from the cortex and often becomes calcified It is most common in the early thirties of life Gliomata are usually single and are frequently the site of degeneration and hemorrhage

*Endothelioma* (fibroblastoma meningioma) is a relatively benign tumor which usually arises from the arachnoid villi and may occasionally become calcified when it is called a psammoma It occurs most commonly in the middle years of life A large majority are found in the anterior two-thirds of the skull They may be found close to the falx in the midline in the Sylvian fissure and on the sphenoidal ridge in the olfactory groove tuberculum sellae or parasellar regions Less commonly they are found on the petrous ridge or in the posterior fossa Fibroblastomata may produce hyperostosis of the cranium or occasionally thinning or even erosion of the bone

*Acoustic fibromata* or *neuromas* are benign circumscribed growths growing from the dural sheath of the eighth nerve They may occur as bilateral angle tumors

*Tuberculomas* may be single or multiple usually the latter and are often secondary to tuberculosis elsewhere in the body although sometimes no other tuberculous focus can be detected They usually have a connective tissue capsule and frequently central caseation occurs Rarely the tubercle becomes calcified and does not produce symptoms A diffuse tuberculous meningitis is often a common end result of a tuberculoma They are found in adults as well as in children grow slowly and occur thoughout the cortex cerebellum and brain stem

*Gummata* are rare and usually multiple

*Adenomata* occur in the pituitary gland and are extremely important in relation to acromegaly and Frohlich s syndrome

*Sarcomata* are either primary or secondary and single or multiple They usually grow from the meninges into the brain and may be encapsulated or invasive They may be secondary from sarcomata elsewhere in the body *Other tumors* such as cholesteatoma dermoid cysts and teratomata are rare

*Carcinomas* are always secondary, grow rapidly are usually multiple and quite vascular The presence of carcinoma elsewhere in the body should always be ruled out before operating upon a brain tumor suspect This is especially important when a person is above the age of forty years as sometimes the intracranial manifestations may be the earliest evidence of carcinoma

*Angiomata* arise from the blood vessels of the meninges and may be associated with birthmarks on the scalp or face Angiomata are especially likely to be seen in the precentral region *Lindau s disease* consists of angioma of the brain and angiomatosis of the retina

The *cause* of brain tumors is unknown Their relation to trauma is a most important one especially from a medico-legal aspect Endotheliomata undoubtedly sometimes follow trauma The general symptoms of a brain tumor may be abruptly brought on by head injury but it is extremely doubtful if the tumor itself can be produced by trauma

*Symptoms* —The expressions of brain tumors are both general and focal The most constant symptom is headache and while it may be occasionally absent it practically always occurs sometime in the history of the case Severe *headache* especially if associated with dizziness and vomiting should always arouse suspicion of a cerebral neoplasm The headache is usually generalized but may be located either in the occipital or frontal regions when it may be associated with local tenderness Headache is due to stretching of the dural blood vessels *Choked disk* or papilledema is a frequent sign of brain tumor but may not occur until late in the course The presence of choked disk indicates a brain tumor in at least 90 per cent of cases and the burden of the proof is on him who propounds another diagnosis Choked disk is most frequently seen with tumors which block the ventriculo subarachnoid pathways and cause increased ventricular pressure it is an extremely common sign in tumors in the posterior fossa Papilledema is usually bilateral but frequently is more pronounced on one side A

nystagmus may be seen in the chronic form Paralysis of the seventh nerve may take place, and other cranial nerves may be implicated The condition may subside or meningitis or brain abscess follow

Signs of meningitis make it imperative to perform a lumbar puncture Only enough fluid should be withdrawn however to determine the color and transparency to count the cells and make a smear for organisms The fluid may contain an excess of cells and no organisms

The outlook in cases of sinus thrombosis is serious Penicillin sulfa compounds, and other antibiotics should be given immediately Septic foci must be drained surgically Ligation of the facial vein may be employed as a prophylaxis against the involvement of the cavernous sinus

## CEREBRAL ANEURYSM

Cerebral aneurysms are most frequently congenital in origin and are due to defects in the development of the cerebral blood vessels Most common are the miliary type which are found at the base of the brain at the points of bifurcation of branches of the arteries composing the circle of Willis Occasionally, congenital arterio-venous aneurysms are present Rarely the aneurysms are of infectious (embolic) origin or are the results of syphilitic or arteriosclerotic involvement of the vessels The arteries at the base of the brain are more frequently involved and aneurysms are likely to be multiple They are usually small but occasionally attain a fairly large size before rupturing The parts of the brain in the immediate vicinity of a cerebral anerurysm may undergo a pressure atrophy Trauma may play a role in the production of a cerebral aneurysm and it is certain that sufficient trauma can cause the rupture of a cerebral aneurysm already present

Before the rupture occurs the aneurysm may produce *symptoms* such as headache often referred to the side on which it exists, vomiting and dizziness A murmur may be heard over the skull This may be localized or heard over a widespread area A murmur may also be detected over the skull in rickets, hydrocephalus, hyperthyroidism and occasionally over a neoplasm General signs of increased pressure are rarely found If an aneurysm ruptures, which it may do either spontaneously or as a result of trauma or severe muscular effort, a massive hemorrhage may occur Slow bleeding may take place into the subarachnoid space If the aneurysm is near the ventricular system and ruptures into it signs of intraventricular hemorrhage will exist Aneurysms of the large vessels of the brain other than those at the base will produce symptoms referable to the parts of the brain involved The optic and olfactory nerves may be compressed by an aneurysm of the anterior cerebral artery and an aneurysm of the internal carotid may affect the ocular nerves in addition to the optic and olfactory and even occasionally the fifth If the aneurysm perforates into the cavernous sinus pulsating exophthalmos may occur

The *diagnosis* of cerebral aneurysm is sometimes difficult but if suspected confirmation may usually be obtained by angiography In a patient suffering from subarachnoid bleeding non traumatic in origin it is fair to assume the hemorrhage has been due to the rupture of a small aneurysm The treatment in general, is that of subarachnoid hemorrhage and of cerebral hemorrhage Surgical intervention may be helpful

## BRAIN TUMORS

Brain tumors comprise from 1 to 2 per cent of all neurologic disorders The tumor may be primary in the brain and its appendages or metastatic from a neoplasm elsewhere in the body

*Pathology* —The most common brain tumors are *gliomas* which comprise from 40 to 50 per cent of all intracranial neoplasms Various types of glioma are to be distinguished Glioblastoma multiforme (gliosarcoma—spongioblastoma multiforme) is usually seen in middle life occurs in the hemispheres is malignant and attains large size An astrocytoma is more benign has a tendency to become cystic and may involve the cerebrum or cerebellum It occurs usually in children or in young adults A medulloblastoma is a rapidly growing neo-

reasonable amount of antisyphilitic therapy the possibility of a nonspecific tumor should be suspected Hydrocephalus either acute or chronic may produce symptoms closely resembling those of a brain tumor The history and the usual absence of focal signs will help to clear up the diagnosis If a case of multiple sclerosis begins abruptly especially with visual changes optic neuritis and other focal signs, such as Jacksonian epilepsy it may be misdiagnosed and operated upon for brain tumor

*Roentgen Diagnosis* —L P Pendergrass of the University of Pennsylvania has kindly written the following

The roentgen examination of the head is extremely valuable in the diagnosis of tumors of the vault and of the brain Tumors of the vault can be easily demonstrated by the changes that occur in the bones that make up the skull such as fibroblastomas and osteomas Bone disease such as syphilis tuberculosis and fibrosing osteitis is also easily demonstrable and the appearance of these diseases is usually easily differentiated In diagnosing intracranial lesions there are two groups sellar and extrasellar One can diagnose a pituitary tumor in approximately 97 per cent of the cases and possibly the percentage may be increased when there is a correlation of clinical and roentgenologic findings The diagnosis of an extrasellar tumor is somewhat more difficult and depends upon several factors (1) Calcification within the tumor is seen in some gliomas endotheliomas Rathke s pouch tumors and rarely in tuberculoma (2) The changes in the dorsum sellæ are due to pulsation from a dilated third ventricle such as occurs in tumors involving the pineal the angle fourth ventricle and cerebellum In fact anything that will block the ventricular system will show ultimately an atrophy of the dorsum sellæ Another valuable sign is the displacement of the pineal body This may be of localizing evidence

The injection of air into the ventricles is a decided help in some cases *Encephalography* is a risky procedure in a brain tumor suspect and should under no circumstances be done if clinical and manometric signs of greatly increased pressure exist (*See* page 1405)

*Lumbar Puncture* —Whether or not a lumbar puncture should be done in patients suffering from cerebral neoplasm is a disputed point It is not as dangerous as some writers contend If the spinal tap is done carefully a small needle used and little fluid withdrawn and the pressure is not elevated above 200 mm of water, little danger will ensue to the patient The great risk of this procedure is in tumors in the posterior fossa Quite a few of these patients succumb suddenly due to respiratory failure Under no circumstances should a large amount of fluid be taken out if the spinal pressure is elevated but enough can be removed so that the important laboratory examinations on the fluid may be performed In a patient suspected of having a tumor and without choking an examination of the spinal fluid is indicated, not only for pressure but also for syphilis

Bárány Tests —Bárány tests are of great value in localizing lesions in the cerebellopontile angle or in saying that a tumor does not exist in that region Otherwise little help is obtained from these tests

Electroencephalography is occasionally of help in localizing the tumor particularly when the growth is superficially located Recent demonstration that intracranial neoplasms tend to concentrate radioactive substances injected into the body gives promise that another helpful and valuable diagnostic technique may be developing

*Treatment* —The treatment of brain tumors is surgical Brilliant results may be obtained especially when the lesion is growing from the brain coverings although most cases do poorly Roentgen ray treatment is of value in a small group The most important point in the treatment of an intracranial lesion suspected of being a tumor is to withhold operation, until the diagnosis is reasonably certain

## INJURIES OF THE BRAIN

In the analysis of a patient suffering from head injury it is important to know the following

1 The length of the period of unconsciousness

2 Whether paralysis or other localized cerebral symptoms existed

high degree of choked disk may be present without much loss in visual acuity, although, as a rule, the condition leads to changes in the visual fields, later impairment of vision, which may go on to blindness and secondary optic atrophy develops Blindness may occur suddenly Choked disk is extremely uncommon in tumors of the pituitary which produce, as a rule, primary optic atrophy *Vomiting* may occur at any time and is a particularly common symptom in the tumors of the posterior fossa, it is due to irritation of the centers in the medulla Vomiting is not as a rule, associated with nausea it has no relation to meals and may or may not be of the projectile type Hiccoughing is a rare symptom *Dizziness* as a symptom of brain tumor is frequently due to neoplasm in the posterior fossa and those which involve the vestibular pathways Sudden change of position may induce vertigo especially if the tumor is in the fourth ventricle

*Convulsions* may occur at any time in the history of a neoplasm Their occurrence after the age of twenty five or thirty years should arouse the suspicion of a brain tumor Attacks simulating petit mal loss of consciousness and status epilepticus may sometimes be seen in brain tumors Jacksonian fits and partial continuous epilepsy are of focal rather than general significance Disturbance in the rhythm of the pulse and respiration occur most frequently due to tumors in the posterior fossa and are due to medullary compression The pulse becomes slow and the respiratory rate is decreased even Cheyne-Stokes breathing may be seen Sudden respiratory failure is a fairly common cause of death in brain tumor and in such cases the heart may continue to beat for some time after respiration has ceased Mental changes occur as the general symptoms of brain tumor but have little localizing value

Alteration of the temperature which may be either subnormal or increased is a rare symptom of a brain tumor but hyperthermia may occur in tumors in the region of the third ventricle Glycosuria and diabetes insipidus are focal rather than general symptoms

*Localizing Symptoms* —It is important to record the symptoms and signs in the order of their development The earlier a symptom or sign appears, the more important it is from a focal standpoint Late appearing symptoms have to be largely discounted For example, the occurrence of a sixth nerve palsy early in the history of a brain tumor may have some importance as a focalizing sign but if it occurs late it may be and usually is due to general increase of intracranial pressure Sometimes a posterior fossa tumor produces symptoms referable to the frontal lobes and the exact reverse may occur It is not infrequent that well marked general symptoms of a brain tumor exist and few, if any, localizing signs are seen The onset of the general and localizing symptoms in a brain tumor are usually insidious but occasionally they may occur with epileptiform suddenness

Acute alcoholism and injury to the head often serve as the precipitating factor Cases of hemiplegia supposedly due to vascular disease, and associated with choked disk are often instances of brain tumors with sudden onset

The existence of choked disks is extremely important It occurs in at least 80 per cent of brain tumors and if present usually indicates a neoplasm Papilledema may also occur in sinus thrombosis sinusitis meningitis and encephalitis Unilateral choked disk may sometimes be seen on the side of a brain tumor On the other hand it may be due to focal infection Papilledema may occasionally be seen without the general symptoms of a brain tumor Careful studies of the visual fields often give valuable information and should never be neglected

*Diagnosis* —A slowly progressive hemiplegia due to thrombosis of the middle cerebral artery especially that part in the Sylvian fissure may prove troublesome in differentiating it from a brain tumor

Neurosyphilis should always be considered and ruled out before the patient is subjected to operation for brain tumor General paresis especially should be eliminated Occasionally a brain tumor may develop in a syphilitic who has positive laboratory findings in the blood and spinal fluid If such a patient does not improve after a

reasonable amount of antisyphilitic therapy the possibility of a nonspecific tumor should be suspected. Hydrocephalus, either acute or chronic, may produce symptoms closely resembling those of a brain tumor. The history and the usual absence of focal signs will help to clear up the diagnosis. If a case of multiple sclerosis begins abruptly, especially with visual changes, optic neuritis and other focal signs such as Jacksonian epilepsy, it may be misdiagnosed and operated upon for brain tumor.

*Roentgen Diagnosis.*—E. P. Pendergrass of the University of Pennsylvania has kindly written the following:

The roentgen examination of the head is extremely valuable in the diagnosis of tumors of the vault and of the brain. Tumors of the vault can be easily demonstrated by the changes that occur in the bones that make up the skull, such as fibroblastomas and osteomas. Bone disease, such as syphilis, tuberculosis and fibrosing osteitis, is also easily demonstrable, and the appearance of these diseases is usually easily differentiated. In diagnosing intracranial lesions there are two groups, sellar and extrasellar. One can diagnose a pituitary tumor in approximately 97 per cent of the cases, and possibly the percentage may be increased when there is a correlation of clinical and roentgenologic findings. The diagnosis of an extrasellar tumor is somewhat more difficult and depends upon several factors: (1) Calcification within the tumor is seen in some gliomas, endotheliomas, Rathke's pouch tumors and rarely in tuberculoma. (2) The changes in the dorsum sellae are due to pulsation from a dilated third ventricle, such as occurs in tumors involving the pineal, the angle, fourth ventricle and cerebellum. In fact, anything that will block the ventricular system will show ultimately an atrophy of the dorsum sellae. Another valuable sign is the displacement of the pineal body. This may be of localizing evidence.

The injection of air into the ventricles is a decided help in some cases. *Encephalography* is a risky procedure in a brain tumor suspect and should under no circumstances be done if clinical and manometric signs of greatly increased pressure exist. (*See* page 1455.)

*Lumbar Puncture.*—Whether or not a lumbar puncture should be done in patients suffering from cerebral neoplasm is a disputed point. It is not as dangerous as some writers contend. If the spinal tap is done carefully, a small needle used and little fluid withdrawn, and the pressure is not elevated above 200 mm. of water, little danger will ensue to the patient. The great risk of this procedure is in tumors in the posterior fossa. Quite a few of these patients succumb suddenly due to respiratory failure. Under no circumstances should a large amount of fluid be taken out if the spinal pressure is elevated, but enough can be removed so that the important laboratory examinations on the fluid may be performed. In a patient suspected of having a tumor and without choking, an examination of the spinal fluid is indicated not only for pressure but also for syphilis.

Barany Tests.—Barany tests are of great value in localizing lesions in the cerebellopontile angle or in saying that a tumor does not exist in that region. Otherwise little help is obtained from these tests.

Electroencephalography is occasionally of help in localizing the tumor, particularly when the growth is superficially located. Recent demonstration that intracranial neoplasms tend to concentrate radioactive substances injected into the body gives promise that another helpful and valuable diagnostic technique may be developing.

*Treatment.*—The treatment of brain tumors is surgical. Brilliant results may be obtained especially when the lesion is growing from the brain coverings, although most cases do poorly. Roentgen-ray treatment is of value in a small group. The most important point in the treatment of an intracranial lesion suspected of being a tumor is to withhold operation until the diagnosis is reasonably certain.

## INJURIES OF THE BRAIN

In the analysis of a patient suffering from head injury it is important to know the following:

1. The length of the period of unconsciousness.
2. Whether paralysis or other localized cerebral symptoms existed.

3 Whether there was bleeding or escape of cerebrospinal fluid from the orifices especially the ears

4 Whether there is roentgen ray evidence of fracture of the skull

5 Was the spinal fluid bloody?

6 Were there convulsions?

A blow to the head may be followed by a fracture of the skull, injury to the brain or the meninges, cerebral blood vessels or the cranial nerves Injury to the brain may occur in the absence of definite fracture of the skull and the blow producing such injuries may be slight On the other hand many patients suffer from fracture of the skull with little or no involvement of the brain A blow producing fracture of the skull or injury to the brain may be direct or indirect and is usually followed by at least momentary loss of consciousness which may however, be very deep and lasting The commonest kind of fracture is the simple linear type depressed and comminuted ones are infrequently seen A blow on one side of the head may occasionally produce a brain injury on the opposite side (contrecoup) Fracture of the skull due to bullets or shrapnel wounds will vary according to the size of the missile and its velocity In many cases it is likely to cause more or less splintering of the bone The blow to the head with or without fracture may also produce *concussion* In many instances of concussion a simple molecular alteration in the cerebral cells occurs but it is probably true that most cases of concussion are accompanied by actual microscopic changes in the cells with secondary degeneration Numerous hemorrhages may be seen scattered through the brain of a person who has died from concussion The vessels of the brain may be torn and extensive injury and laceration of the brain may be seen A depressed fragment of bone may produce symptoms, as may also blood and the edema which follows a cerebral commotion Either or both tables of the bone may be fractured although the inner one is more usually involved Evidence of local injury to the skull may be present in the form of contusion or laceration and ecchymoses are common about the eyes and the mastoid region Those which occur in the latter area are called Battle's sign which may not appear for a number of hours Bleeding from the orifices of the head usually means fracture at the base and cerebrospinal fluid may escape as the result of such injuries In the presence of a compound or comminuted fracture or a fracture at the base of the skull with escape of blood or spinal fluid from the mouth nose or ears infection of the meninges or actual brain abscess is more likely to occur but such infection may also come on after a simpler fracture The best illustration of a simple concussion of the brain is the knock out punch given to a prize fighter the period of unconsciousness lasting but a few seconds on emerging from unconsciousness the patient may suffer from headache dizziness and vomiting The headache may be occipital frontal or generalized and is often referred to the neck

Vertigo ranks second to headache in frequency as a symptom after cerebral concussion and is often accompanied by nausea and vomiting The patient is irritable lacks concentration complains of poor memory insomnia and lack of energy and inability to work most of these symptoms being especially common in litigation cases and in those who were injured at work and strive to receive compensation It must always be remembered however that even a slight blow on the head may be followed by small hemorrhages scattered through the brain The duration of the symptoms following concussion varies greatly and one of the factors which has important bearing on the length of symptoms is the question of litigation After the acute stage has been passed headache dizziness and fatigue are commonly complained of and the importance of them is difficult to evaluate Investigation by means of the Barany tests in those cases complaining of dizziness occasionally shows evidence interpreted as being due to interference in the function of the vestibular fibers although the importance of such a finding is discounted by many Amnesia for the accident and for the events immediately preceding and following it is common

The *prognosis* in simple concussion of the brain is good one of the most important things on which to base the prognosis is the

length of the period of unconsciousness Cases may be cured only to relapse especially if legal complications occur The desire to get well is an important consideration in a head injury case

*Fracture of the skull* is accompanied by some degree of unconsciousness in practically every case, although the length of unconsciousness may vary from a few minutes to hours or days, and the patient may remain in a stupor until he dies There is usually a swelling at the site of injury and later about the eyes or mastoid region Fracture of the base is especially likely to be accompanied by injury to the cranial nerves especially the sixth seventh and eighth, a general increase of intracranial pressure will produce swelling of the optic nerves The pupils are usually unequal with a dilated pupil on the side of the cerebral injury, although they may be small and fixed to light If a hemorrhage occurs it compresses the brain or if the latter has been contused and is edematous stupor may be profound the pulse slow and the respiratory rate slow and often of the Cheyne-Stokes variety *Focal signs* will depend upon the presence of a depressed fracture collections of blood over the cortex or injury to the brain itself As the patient regains consciousness he is confused amnesic, delirious or even psychotic Korsakoff s psychosis may occur following severe injury to the brain While mental symptoms are of course frequently due to the injury a careful history of the patient s habits as regards alcohol should be obtained because in many instances the mental symptoms are more pronounced and prolonged due to the alcoholic tendencies of the individual The possibility of cerebral syphilis in one of its forms being brought out or aggravated by a head injury should also be borne in mind Not infrequently a man works successfully and intelligently up to the time of his injury from which he passes immediately into the stage of general paresis Brain tumors may be present and produce no symptoms before a head injury and afterward produce marked signs which may be confused with those due to the trauma If the fracture has gone through a sinus or if the dura has been ruptured pneumocephalus may be found on roentgen ray examination Lumbar puncture will often reveal a bloody fluid and sometimes increased pressure When the patient recovers the same symptoms that are found after a concussion are complained of but usually in a more marked degree and as in cerebral concussion, the duration of these symptoms frequently has a direct relationship to the presence or absence of litigation The *mental symptoms* that are seen after a fracture of the skull consist of loss of memory, fatigability, loss of inhibition and of attention and change in personality Mental symptoms of a hysterical nature are occasionally seen Severe injuries to the brain are followed by epilepsy in a certain percentage of cases, which has been estimated from seven to ten per cent The epileptic attacks may be localized or focal in type and while the first fit may occur during the stage of acute injury, it may be delayed a number of years Injury to the motor cortex naturally produces more instances of post traumatic epilepsy than injury to other parts of the brain but implication of parts remote from the motor cortex may be succeeded by convulsions

*Epidural hemorrhage* or *subarachnoid hemorrhages* may occur from a head trauma with or without fracture Bleeding may come on as a result of rupture of the middle meningeal artery or vein or may be due to a tearing of the sinus Just as a fracture of the skull may be produced by a blow on the opposite side so also may a traumatic hemorrhage of the brain occur on the side opposite to that to which the force was applied The frequency of epidural hemorrhage due to bleeding from the middle meningeal supply has been greatly overestimated but the importance of recognizing the syndrome producing it is extremely necessary The typical history is as follows A patient receives a blow on the head which produces momentary unconsciousness he usually though not always recovers and may even resume his work then after a short period he becomes dull stuporous and unconscious, with signs of increased intracranial pressure although the latter may be absent In fact the spinal pressure may be actually lower than normal Weakness may develop on the side opposite to the hemorrhage is progressive and is

3 Whether there was bleeding or escape of cerebrospinal fluid from the orifices especially the ears

4 Whether there is roentgen ray evidence of fracture of the skull

5 Was the spinal fluid bloody?

6 Were there convulsions?

A blow to the head may be followed by a fracture of the skull, injury to the brain or the meninges, cerebral blood vessels or the cranial nerves Injury to the brain may occur in the absence of definite fracture of the skull and the blow producing such injuries may be slight On the other hand, many patients suffer from fracture of the skull with little or no involvement of the brain A blow producing fracture of the skull or injury to the brain may be direct or indirect, and is usually followed by at least momentary loss of consciousness which may, however, be very deep and lasting The commonest kind of fracture is the simple, linear type depressed and comminuted ones are infrequently seen A blow on one side of the head may occasionally produce a brain injury on the opposite side (contrecoup) Fracture of the skull due to bullets or shrapnel wounds will vary according to the size of the missile and its velocity In many cases it is likely to cause more or less splintering of the bone The blow to the head, with or without fracture, may also produce *concussion* In many instances of concussion, a simple molecular alteration in the cerebral cells occurs but it is probably true that most cases of concussion are accompanied by actual microscopic changes in the cells with secondary degeneration Numerous hemorrhages may be seen scattered through the brain of a person who has died from concussion The vessels of the brain may be torn and extensive injury and laceration of the brain may be seen A depressed fragment of bone may produce symptoms as may also blood and the edema which follows a cerebral commotion Either or both tables of the bone may be fractured although the inner one is more usually involved Evidence of local injury to the skull may be present in the form of contusion or laceration, and ecchymoses are common about the eyes and the mastoid region Those which occur in the latter area are called Battle's sign, which may not appear for a number of hours Bleeding from the orifices of the head usually means fracture at the base and cerebrospinal fluid may escape as the result of such injuries In the presence of a compound or comminuted fracture, or a fracture at the base of the skull with escape of blood or spinal fluid from the mouth nose or ears, infection of the meninges or actual brain abscess is more likely to occur but such infection may also come on after a simpler fracture The best illustration of a simple concussion of the brain is the *knock out punch* given to a prize fighter the period of unconsciousness lasting but a few seconds on emerging from unconsciousness the patient may suffer from headache dizziness and vomiting The *headache* may be occipital frontal or generalized and is often referred to the neck

Vertigo ranks second to headache in frequency as a symptom after cerebral concussion and is often accompanied by nausea and vomiting The patient is irritable lacks concentration complains of poor memory, insomnia and lack of energy and inability to work most of these symptoms being especially common in litigation cases and in those who were injured at work and strive to receive compensation It must always be remembered however that even a slight blow on the head may be followed by small hemorrhages scattered through the brain The duration of the symptoms following concussion varies greatly and one of the factors which has important bearing on the length of symptoms is the question of litigation After the acute stage has been passed headache dizziness and fatigue are commonly complained of and the importance of them is difficult to evaluate Investigation by means of the Barany tests in those cases complaining of dizziness occasionally shows evidence interpreted as being due to interference in the function of the vestibular fibers although the importance of such a finding is discounted by many Amnesia for the accident and for the events immediately preceding and following it is common

The *prognosis* in simple concussion of the brain is good one of the most important things on which to base the prognosis is the

## PATHOLOGIC STATES OF THE NERVOUS SYSTEM OCCURRING DURING PREGNANCY AND THE PUERPERIUM

If a woman has any unusual illness during a pregnancy it is usually attributed to that condition but in many instances the neurologic condition is only coincidental. We have seen a number of brain tumors entirely unsuspected in the course of pregnancy. The symptoms resulting from these tumors, namely headache and vomiting, were thought to be due to a toxemia.

The convulsions which occur during pregnancy may be the result of toxic states induced by that condition or they may be the first manifestation of epilepsy. Hysteria may be the cause of fits during pregnancy.

Hemiplegia, an infrequent complication of pregnancy, usually occurs in the last half of the pregnancy and has been reported as occurring during the puerperium coming on one to three weeks after childbirth. The pathology of this form of hemiplegia is obscure although most of the cases are due to venous or arterial thrombosis or embolism; certainly few patients die, which would be the case if the condition were due to hemorrhage. Some of these cases may be due to a toxic factor producing encephalitis more or less limited to the motor cortex. If syphilis is present in the individual the added strain of pregnancy and delivery might readily produce thrombosis of a diseased cerebral vessel. If infection is present in a case of hemiplegia occurring during pregnancy or puerperium the possibility of an abscess or of encephalitis should be considered. Aphasia may also occur and is probably due to the same cause that produces hemiplegia.

Intracranial venous thrombrosis is a rare complication which usually appears between the fourth and the twenty first day after delivery. It is frequently characterized by headache and convulsions and is followed by monoplegia or hemiplegia with or without aphasia. Papilledema and amaurosis may occur. A third to half the patients die; those who survive may show persistent residua. Therapy is symptomatic.

The diagnosis of brain tumor in the course of pregnancy is a difficult one, and fortunately one which is not too frequently encountered. There may exist in pregnancy a type of toxemia producing choked disks, vomiting and the other signs suggestive of increased intracranial pressure. Where a doubt exists as to the presence of a brain tumor in pregnancy it is always wise to wait rather than to rush in with a surgical procedure.

Epidemic encephalitis if occurring during a pregnancy is frequently mistaken for toxemia or for a brain tumor. The choreaform type of encephalitis may be mistaken for chorea occurring during pregnancy. The most difficult differentiation is between epidemic encephalitis and toxemia. Careful and repeated laboratory examinations including that of the spinal fluid may be necessary. The occurrence of an ocular or of other cranial nerve palsies points directly toward encephalitis as the diagnosis.

Choreiform movements which occur during pregnancy may be due to chorea, encephalitis or rarely hysteria. The majority of cases appear in the first six months and are more frequent in women under the age of twenty five years. The mortality in this type of chorea has been estimated from 15 to 20 per cent.

Chorea gravidarum is likely to be more severe than Sydenham's chorea. Just as there is no mental disease peculiar to pregnancy and the puerperium it is likely that there is no chorea peculiar to these states. If hysteria and encephalitis have been ruled out, the instances of chorea are of Sydenham's type.

Peripheral multiple neuritis may complicate pregnancy or the puerperium. Such cases occurring in women who are not alcoholic are due to infections or to vitamin deficiency or to both. A psychosis may accompany the polyneuritis, as usually of the toxic type and may be of the Korsakoff variety.

Involvement of the optic nerve is usually of the toxic type secondary to kidney involvement. Real choking of the disks, however, may be seen as the result either of toxemia or of brain tumor. Disturbance of vision of various types may occur, the most

frequently accompanied by twitching or convulsions The pulse and respirations are slow, and the respirations may be of the Cheyne Stokes type Signs of pyramidal tract disease are present on the paralyzed side, although if the parietal cortex is involved, the deep reflexes may be lost Signs of meningitis are not usually present although if bleeding also occurred at the base the neck may be stiff A dilated pupil frequently exists on the side of the hemorrhage due to pressure on the third nerve by the uncus which herniates through the incisura of the tentorium

In the *diagnosis* the history is most important The treatment of the vast majority of head injuries is medical the great exception is rupture of the middle meningeal artery where prompt and efficient surgery may be lifesaving Complete rest an ice bag to the head, sedatives if the patient is restless or delirious but not in doses large enough to becloud the symptoms a continuous tub if maniacal excitement exists moderate *limitation of fluid and magnesium* sulphate by mouth or rectum is the treatment usually pursued Antibiotics should be administered to prevent the development of meningitis and pneumonia Physical restraint may be necessary

*Acute or chronic subdural hematoma* is a collection of blood between the dura and the arachnoid membranes as a rule over the convexity of the cerebral hemisphere The blow to the head responsible for the condition may be severe or extremely trivial The latent period between the receipt of the blow and the *appearance of symptoms* may vary from hours to months and according to some more than a year In some persons the lesion is bilateral In addition to trauma it may occur in such conditions as general paresis, in hemorrhagic diathesis in infections and in alcoholics but in these cases it is likely that a forgotten blow may have been the real cause of the bleeding The bleeding is originally venous and is usually small in amount The trapped blood breaks down into simpler protein molecules and by osmosis absorbs fluid from the subarachnoid space With time the hematoma enlarges and symptoms develop The inner surface of the dura is thickened either locally, or more or less extensively A combination of hemorrhage and reparative activity leads in time to marked thickening of the inner layer of the dura with adherence to the arachnoid The contents of the hemorrhagic cysts vary from a thin yellowish brown fluid to a firm clot External hydrocephalus will be pronounced The onset of *symptoms* may be apoplectiform or insidious Mental symptoms consisting of dulness irritability and delirium are common, and headache vomiting and convulsions are frequently seen The convulsions may be either focal or general Stupor, followed by pronounced coma with slow pulse and respiratory rate or Cheyne Stokes breathing may occur Signs of meningeal irritation, hemiplegia or monoplegia and papilledema are seen in some cases The hemiplegia may be present on the side of the lesion due to pressure on the opposite crus Automatic states and amnesia, disturbances of speech and of vision may be present if the hemorrhage involves other *specialized areas Fracture of the skull may* or may not be demonstrated by roentgen ray examination

The *spinal fluid* shows as a rule increased pressure may be bloody or simply xanthochromic The deep reflexes are frequently unequal usually increased but if the parietal cortex is involved they may be absent on the contralateral side Cranial nerve symptoms are usually discovered if hemorrhage has occurred at the base Dilatation of one pupil most often on the side of the hemorrhage is common There may be localized tenderness to percussion of the skull The *diagnosis* is not easy Coma may deepen or disappear in remissions The *treatment* of the condition is surgical

Both sides of the skull should be trephined because of the frequency of bilateral hematomas In any case in which the diagnosis is obscure or if the patient is supposed to have had a stroke which presents symptoms and signs that are unusual or peculiar the head should be opened this recommendation is made despite the fact that the *authors are constitutionally opposed to fishing expeditions*

## PATHOLOGIC STATES OF THE NERVOUS SYSTEM OCCURRING DURING PREGNANCY AND THE PUERPERIUM

If a woman has any unusual illness during a pregnancy it is usually attributed to that condition but in many instances the neurologic condition is only coincidental. We have seen a number of brain tumors entirely unsuspected in the course of pregnancy. The symptoms resulting from these tumors, namely headache and vomiting were thought to be due to a toxemia.

The convulsions which occur during pregnancy may be the result of toxic states induced by that condition or they may be the first manifestation of epilepsy. Hysteria may be the cause of fits during pregnancy.

Hemiplegia an infrequent complication of pregnancy usually occurs in the last half of the pregnancy and has been reported as occurring during the puerperium coming on one to three weeks after child birth. The pathology of this form of hemiplegia is obscure although most of the cases are due to venous or arterial thrombosis or embolism certainly few patients die which would be the case if the condition were due to hemorrhage. Some of these cases may be due to a toxic factor producing encephalitis more or less limited to the motor cortex. If syphilis is present in the individual the added strain of pregnancy and delivery might readily produce thrombosis of a diseased cerebral vessel. If infection is present in a case of hemiplegia occurring during pregnancy or puerperium the possibility of an abscess or of encephalitis should be considered. Aphasia may also occur and is probably due to the same cause that produces hemiplegia.

Intracranial venous thrombrosis is a rare complication which usually appears between the fourth and the twenty first day after delivery. It is frequently characterized by headache and convulsions and is followed by monoplegia or hemiplegia with or without aphasia. Papilledema and amaurosis may occur. A third to half the patients die those who survive may show persistent residua. Therapy is symptomatic.

The diagnosis of brain tumor in the course of pregnancy is a difficult one and fortunately one which is not too frequently encountered. There may exist in pregnancy a type of toxemia producing choked disks vomiting and the other signs suggestive of increased intracranial pressure. Where a doubt exists as to the presence of a brain tumor in pregnancy it is always wise to wait rather than to rush in with a surgical procedure.

Epidemic encephalitis if occurring during a pregnancy is frequently mistaken for toxemia or for a brain tumor. The choreiform type of encephalitis may be mistaken for chorea occurring during pregnancy. The most difficult differentiation is between epidemic encephalitis and toxemia. Careful and repeated laboratory examinations including that of the spinal fluid may be necessary. The occurrence of an ocular or of other cranial nerve palsies points directly toward encephalitis as the diagnosis.

Choreiform movements which occur during pregnancy may be due to chorea encephalitis or rarely hysteria. The majority of cases appear in the first six months and are more frequent in women under the age of twenty five years. The mortality in this type of chorea has been estimated from 15 to 20 per cent.

Chorea gravidarum is likely to be more severe than Sydenham's chorea. Just as there is no mental disease peculiar to pregnancy and the puerperium it is likely that there is no chorea peculiar to these states. If hysteria and encephalitis have been ruled out the instances of chorea are of Sydenham's type.

Peripheral multiple neuritis may complicate pregnancy or the puerperium. Such cases occurring in women who are not alcoholic are due to infections or to vitamin deficiency or to both. A psychosis may accompany the polyneuritis is usually of the toxic type and may be of the Korsakoff variety.

Involvement of the optic nerve is usually of the toxic type secondary to kidney involvement. Real choking of the disks however may be seen as the result either of toxemia or of brain tumor. Disturbance of vision of various types may occur the most

dramatic of which is sudden blindness. Occasionally retrobulbar neuritis may be seen in pregnancy. The presence of sinus disease, other sources of toxemia besides pregnancy, and hysteria should be considered. Changes in the visual fields, especially on the temporal sides, may occur in pregnancy and may be due to the enlargement of the pituitary gland. Paralysis of the motor cranial nerves is rare in pregnancy and the puerperium, but ophthalmoplegia and extra-ocular muscle palsies may occur in the polioencephalitis hemorrhagica superior of Wernicke, which sometimes accompanies hyperemesis gravidarum. This condition is due to vitamin deficiency, particularly lack of thiamin. Involvement of the spinal cord may occur at any time during pregnancy or the puerperium and may be the result of toxemia, infection, or of the severe strain of delivery. Most authorities believe that while some of the forms of myelitis or paralysis due to spinal cord disease which occur during pregnancy are secondary to such conditions as syphilis or disease of the vertebræ, the extraordinary exertion and strain incident to delivery may produce changes in the vessels of the cord. Myelitis has been known to occur in three successive pregnancies in the same woman.

## DISORDERS OF THE CENTRAL NERVOUS SYSTEM OCCURRING AT BIRTH

*Injury* to the central nervous system during birth is common and accounts for a large percentage of the deaths of babies. Blood found in the spinal fluid immediately after birth usually means injury. This does not necessarily imply that the obstetrician is in any way at fault. The usual cause is disproportion between the baby and the birth canal. Injury to the central nervous system during birth is a common cause of infantile hemiplegia, cerebral diplegia and other spastic states, the various grades of feeblemindedness and epilepsy. Though injuries to the cord are less frequently seen, they may occur in breech deliveries or in babies on whom version was practised. Another cause for injury to the brain at birth is prolonged labor with asphyxiation.

The *symptoms* of birth injury will of course depend upon the location of the injured part. The lesions most frequently involve the basal regions with the resulting symptoms of tremor, rigidity and athetosis. In these cases a diagnosis of cerebral diplegia is frequently made. If the pyramidal system has been involved on one or both sides, symptoms of such involvement will be found. A hemorrhage may occur only one one side and in such a case will produce infantile hemiplegia. The fact that the child has hemiplegia is often not recognized until it should be sitting up or walking. Convulsions are especially likely to occur in children who have had a cerebral injury. Many children who have suffered from diffuse cerebral hemorrhage without exact localizing signs are found to be late in walking and talking and show arrested cerebral development. On the other hand, a child who has had hemiplegia, the result of an injury at birth, may show little or no mental deficiency.

Implication of the spinal cord as the result of birth injury is more often due to obstetrical interference. The cord may be completely ruptured or may be the seat of partial disintegration. If the involvement is high, death as a rule results quickly. Children born prematurely may show symptoms which are confused with birth injury. The child born prematurely is a bad risk and may show signs of lack of cerebral development, and is often late in walking and talking. The pyramidal tracts are late in developing and may never develop fully. This will result in spastic paraplegia. Infection occurring in the first few weeks of life may produce inflammatory reactions in the central nervous system which are thought to be traumatic.

The *diagnosis* is difficult and much depends upon a proper history. The duration of labor, whether or not the child cried promptly after birth or gave evidence of asphyxiation, are all extremely important considerations. The occurrence of an acute infection of any description in the first few weeks of life is also important. Of equal significance is the health of the mother during pregnancy, especially whether or not she had suffered a severe infectious disease

Certain neurologic conditions occurring early in life such as hydrocephalus, microcephalus, spinal bifida various forms of muscular atrophy occurring in children and hereditary ataxia must be differentiated from birth injuries Children born after a long and difficult labor especially if instruments were used, should be subjected to careful physical examination from the neurologic standpoint In many instances a lumbar puncture may be necessary to aid in the diagnosis

If an intracerebral hemorrhage exists it must be *treated* accordingly If however, blood is found in the spinal fluid and the examination does not indicate that the hemorrhage has occurred into the brain the patient should be treated as one of subarachnoid bleeding Decompressive operations should be resorted to only as a last resort and will usually be unavailing If, however signs exist pointing to a localized hemorrhage surgery should be given a chance Occasionally a baby who has an extracerebral hematoma will develop enlargement of head simulating hydrocephalus operation is indicated in such cases If the child survives to the age of three or four years or beyond he will often be found to be a case for speech training and frequently will have to be sent to a special school depending upon the amount of intellectual damage done If infantile hemiplegia results various orthopedic operations may assist the child in making the greatest use of the power which exists but is unavailable because of contractures On the other hand patients are subjected to operation without beneficial result While carefully considered physiotherapeutic exercises and orthopedic operations may be of value in enabling the child with cerebral palsy to make the best use of such functioning muscle power as he has it must be borne in mind that no amount of retraining or surgery will restore the damaged neural tissues

### Internal Hydrocephalus

Internal hydrocephalus is a condition in which there is an increase in the amount of fluid within the ventricles of the brain with consequent enlargement of the ventricles The total amount of fluid under normal conditions varies from 100 to 200 cc An unusual rate of production or an interference with the outward flow leads to hydrocephalus The usual cause of this condition is a block somewhere along the closed system in which the fluid circulates but it may also be due to an excessive production or inadequate absorption of the spinal fluid The usual location of the block is in the region of the fourth ventricle In this case all of the ventricles are enlarged If the escape of the fluid is interfered with at the arachnoid villi there is free circulation through the ventricles, but the fluid cannot be absorbed through the sinuses This produces both internal and external hydrocephalus The cause of internal hydrocephalus which is the common variety may be a congenital anomaly tumor infection or injury The common infection is meningitis, which causes adhesions around the foramina of Magendie and Luschka and prevents the escape of fluid from these orifices In such cases it is difficult to obtain much spinal fluid by lumbar puncture Tumors in the posterior fossa frequently produce internal hydrocephalus as may also tumors in or close to the ventricular system Injuries producing bleeding in the subarachnoid space particularly at birth may lead to adhesions and the formation of an obstructive type of hydrocephalus Congenital syphilis tuberculous parentage rickets and heredity at times play a role in the production of hydrocephalus

The *symptoms* of hydrocephalus are usually present in some degree at birth which may be difficult or impossible because of the size of the head The circumference of the head normally is 35 to 40 cm at birth may be increased two or three times in hydrocephalus The skull is round the frontal end is prominent the sutures are separated and the fontanels are wide and often pulsate The scalp is thin and the patient has little or no hair The face in contrast to the skull seems small and triangular The scleræ are visible and the eyes are widely separated The child is a poor specimen physically may be hemiplegic or paraplegic and if it learns to walk at all it does so late Convulsions and optic atrophy are common Various grades of

*retarded mentality are found* from the rare case which is almost normal to low grade idiots These patients are extremely susceptible to infections, and as a rule die early in life Hydrocephalus is often associated with other peculiarities of development, such as spinal bifida or encephalocele

The *diagnosis* should offer little difficulty The injection of dyes may be used to determine whether the hydrocephalus is communicating or obstructive The dye is injected into one of the lateral ventricles If the hydrocephalus is of the communicating type, it will be recovered by the lumbar puncture If there is no recovery of the fluid from the lumbar tap, there is an obstruction somewhere in the ventricular system Encephalography or ventriculography may be used to obtain a detailed picture If hydrocephalus occurs after the sutures are closed signs of increased intracranial pressure ensue These cases are practically always due to *meningitis or tumor although* rarely fracture of the base with subarachnoid bleeding may block the escape of fluid

The *treatment* of hydrocephalus usually produces no satisfactory results Although a few good results have been reported by surgical procedures in which new openings are made for the escape of fluid such as that from the third ventricle into the underlying cistern or cauterization of the choroid *most of the procedures recommended are* palliative If syphilis is present antiluetic treatment should be pushed

### Infantile Hemiplegia

As a result of trauma or asphyxiation during birth or due to encephalitis the result of infections of practically any variety or to an embolism an infant may become hemiplegic This will make the child slow in walking and talking and a candidate for epilepsy If the hemiplegia is on the right side, speech if present may be lost but may be regained or reappear probably by the training of the centers on the opposite side of the brain If the hemiplegia is produced by encephalitis occurring in the cortex Jacksonian epilepsy or partial continuous epilepsy may be present If hemiplegia develops in an infant the limbs on the paralyzed side do not develop and are smaller and shorter than *their fellows and there* is a marked tendency toward contractures at the wrist fingers and ankle In this type of case orthopedic operations may do considerable good although these procedures are certainly not underdone

### Little s Disease

In infants born prematurely and sometimes in twins the pyramidal tracts fail to develop properly As a result spastic paraplegia with signs of pyramidal tract disease exists The upper extremities may be involved but not to the extent of the lower In other cases the upper extremities escape entirely and the mentality of the child may be normal In some instances there is a general arrest of cerebral development the mentality of the child is greatly affected and the speech may be restricted or absent Convulsions occasionally occur While children suffering from this condition are late in walking they may develop a fair gait

The causes of the various types of paralysis that occur in infants are somewhat beclouded The factors at fault are defective genes premature birth difficult and prolonged labor especially instrumental ones and asphyxiation Acute infectious disease of the mother during pregnancy may account for changes in the central nervous system of the fetus and acute infections of the child in the first few weeks of life may produce encephalitis which subsequently leads to various types of paralysis Convulsions occurring early in life may be followed by a cerebral hemorrhage *Epilepsy various grades of mental retardation* speech defects ocular palsies and irregular movements especially athetosis are common complications Occasionally the cerebellum seems to be particularly involved

### Tay-Sachs Disease

Amaurotic family idiocy (Tay-Sachs disease) is a combination of blindness from optic atrophy and idiocy from arrested cerebral development A child who appears normal at birth shows the foregoing symptoms usually in the first year of *life It is particularly common* in Polish Jewish children The condition is often familial Gradual signs of cerebral diplegia occur with nystagmus and diminution of vision followed by blindness The course of the condition is rapid the child usually dying before the age of six years One of the most characteristic signs in the examination of the patient is a cherry red spot seen at the macula This is due to atrophy of the retina which permits the choroid to shine through

## BULBAR AND PSEUDOBULBAR PALSY

### Bulbar Palsy

This condition is frequently a part of the picture of amyotrophic lateral sclerosis progressive spinal muscular atrophy acute anterior poliomyelitis and may be the first symptom of these conditons It comes on as a rule during or after the fifth decade in nonpoliomyelitic cases The pathologic changes consist of degeneration of the lower nuclei of the seventh the ninth, tenth and twelfth cranial nerves The upper parts of the seventh nerve nuclei occasionally and at times the motor fifth are implicated The *symptoms* are difficulty in speaking swallowing chewing and phonation coming on gradually The speech develops a nasal twang The labials and linguals are pronounced with difficulty and the speech gradually becomes worse and worse so that in time anarthria results The same thing takes place as far as swallowing is concerned so that in time food may regurgitate through the nose or lodge in the larynx A progressive atrophy occurs in the muscles of the lips tongue larynx and also in those of mastication All the signs of anterior horn disease occur in the atrophic muscles

The *diagnosis* is to be made from pseudo bulbar palsy encephalitis or myasthenia gravis which is in reality bulbar palsy without anatomic findings Tumors of the bulb must also be differentiated

There is no successful *treatment* and the patient usually succumbs within two years of the onset

### Pseudobulbar Palsy

Strictly speaking this is not a disease but a syndrome depending upon bilateral cerebral lesions involving the upper motor neurons These lesions are usually the result of vascular disease with encephalomalacia Any one of the numerous processes which may produce bilateral lesions in the brain may be the etiologic fault thus arteriosclerosis syphilis chronic encephalitis multiple sclerosis and multiple emboli may be the cause of pseudobulbar palsy

The movements which are controlled bilaterally from the cortex are not markedly involved by a unilateral lesion thus in the ordinary type of hemiplegia swallowing and chewing are little affected and usually only early in the illness In bilateral lesions, however these functions are interfered with In a pseudobulbar palsy the lesions are above the nuclei and the symptoms of anterior horn disease seen in bulbar palsy are lacking In pseudobulbar palsy the patient has a spastic involvement of the muscles supplied by the bulb

The history of the onset is most important It is discovered that the patient has had at least two apoplectic attacks one involving each side of the body and it is frequently true that one of the attacks was mild In some of the patients the hemiplegia lasts only a short time After bilateral lesions have occurred the patient develops difficulty in chewing, swallowing and talking Difficulty in chewing and swallowing may be so pronounced that the patient has trouble obtaining enough nourishment He frequently chokes and food may regurgitate through the nose The difficulty in speech may vary from a mild dysarthria to anarthria Attacks of involuntary emotionalism are common and the patient may have uncontrollable laughter or crying without cause Anything which plays upon the emotions of the individual may serve to bring further involuntary laughter or crying especially is this so of the latter

Signs of pyramidal tract disease may be present on both sides of the body and the gait may be characteristic of cerebrospinal arteriosclerosis namely the gait of little steps it may be spastic on one or both sides In pseudobulbar palsy one may also see *symptoms* referable to any part of the brain These symptoms will of course depend upon the location of the pathologic lesions Disturbance in the control of the sphincters may also be present

The *diagnosis* of pseudobulbar palsy is usually easy and is made on the history the involuntary emotionalism difficulty in chewing and swallowing and talking without the signs of nuclear disease Occasionally pseudobulbar palsy with attacks of involun-

retarded mentality are found, from the rare case which is almost normal to low grade idiots These patients are extremely susceptible to infections and as a rule die early in life Hydrocephalus is often associated with other peculiarities of development, such as spinal bifida or encephalocele

The *diagnosis* should offer little difficulty The injection of dyes may be used to determine whether the hydrocephalus is communicating or obstructive The dye is injected into one of the lateral ventricles If the hydrocephalus is of the communicating type it will be recovered by the lumbar puncture If there is no recovery of the fluid from the lumbar tap there is an obstruction somewhere in the ventricular system Encephalography or ventriculography may be used to obtain a detailed picture If hydrocephalus occurs after the sutures are closed signs of increased intracranial pressure ensue These cases are practically always *due to meningitis or tumor although* rarely fracture of the base with subarachnoid bleeding may block the escape of fluid

The *treatment* of hydrocephalus usually produces no satisfactory results Although a few good results have been reported by surgical procedures in which new openings are made for the escape of fluid such as that from the third ventricle into the underlying cistern or cauterization of the choroid most of the procedures recommended are palliative If syphilis is present antiluetic treatment should be pushed

### Infantile Hemiplegia

As a result of trauma or asphyxiation during birth or due to encephalitis the result of infections of practically any variety or to an embolism an infant may become hemiplegic This will make the child slow in walking and talking and a candidate for epilepsy If the hemiplegia is on the right side speech if present may be lost but may be regained or reappear probably by the training of the centers on the opposite side of the brain If the hemiplegia is produced by encephalitis occurring in the cortex Jacksonian epilepsy or partial continuous epilepsy may be present If hemiplegia develops in an infant the limbs on the paralyzed side do not develop and are smaller and shorter than their fellows and there is a marked tendency toward contractures at the wrist, fingers and ankle In this type of case orthopedic operations may do considerable good although these procedures are certainly not underdone

### Little s Disease

In infants born prematurely and sometimes in twins the pyramidal tracts fail to develop properly As a result spastic paraplegia with signs of pyramidal tract disease exists The upper extremities may be involved but not to the extent of the lower In other cases the upper extremities escape entirely and the mentality of the child may be normal In some instances there is a general arrest of cerebral development the mentality of the child is greatly affected and the speech may be restricted or absent Convulsions occasionally occur While children suffering from this *condition are late in walking they may develop* a fair gait

The causes of the various types of paralysis that occur in infants are somewhat beclouded The factors at fault are defective genes premature birth difficult and prolonged labor especially instrumental ones and asphyxiation Acute infectious disease of the mother during pregnancy may account for changes in the central nervous system of the fetus and acute infections of the child in the first few weeks of life may produce encephalitis which subsequently leads to various types of paralysis Convulsions occurring early in life may be followed by a cerebral hemorrhage Epilepsy various grades of mental retardation speech defect ocular palsies and irregular movements especially athetosis are common complications Occasionally the cerebellum seems to be particularly involved

### Tay Sachs Disease

Amaurotic family idiocy (Tay Sachs disease) is a combination of blindness from optic atrophy and idiocy from arrested cerebral development A child who appears normal at birth shows the foregoing symptoms usually in the first year of life It is particularly common in Polish Jewish children The condition is often familial Gradual signs of cerebral diplegia occur with nystagmus and diminution of vision followed by blindness The course of the condition is rapid the child usually dying before the age of six years *One of* the most characteristic signs in the examination of the patient is a cherry red spot seen at the macula This is due to atrophy of the retina which permits the choroid to shine through

lethargy, and clouding of consciousness. In addition there are varying degrees of ophthalmoplegia, ataxia and tremor. There may be an associated peripheral neuropathy. In untreated cases the course is rapidly progressive, stupor deepens and death ensues. Large doses of thiamin and other vitamins produce improvement particularly of the *ophthalmoplegia*, but many of the recovered cases show a Korsakoff's psychosis.

## DISEASES DUE TO DISORDERS OF THE EXTRAPYRAMIDAL MOTOR SYSTEM

### PARALYSIS AGITANS

*Synonyms.*—Parkinson's disease. Shaking palsy.

*Definition.*—Paralysis agitans is a chronic, slowly progressive disorder characterized by tremor and rigidity and due to changes in the extrapyramidal motor system.

A definite *etiologic factor* has never been found, although the Parkinsonian syndrome is extremely common after epidemic encephalitis and is due in such cases to inflammatory changes. It may be that many of the cases that we consider ordinary paralysis agitans are in reality due to infections which caused encephalitis years before the onset of the symptoms of paralysis agitans. This is particularly true in the juvenile types of the disease. Others are of the opinion that the disease is primarily a degenerative disorder not unlike that occurring in the cerebral cortex in senile dementia. Although hereditary and familial forms have been reported, they are extremely uncommon. Men are affected much more frequently than women and the disease usually appears after the age of forty five years. Emotions and injuries have been mentioned as etiologic factors. In the latter case it is likely small hemorrhages occur in the basal ganglia. Syphilis probably plays very little if any role in the production of paralysis agitans. Large tumors in the frontal areas of the brain may very rarely produce Parkinsonism.

*Symptoms.*—These appear insidiously and little change may take place for weeks or months. In the early stage of the disease the tremor, which is usually the first symptom to be noticed, may disappear for a short time. The tremor as a rule first appears in an upper extremity and practically always in the hand or fingers. It is rhythmical, may be either fine or coarse and vibrations range from four to seven a second. In the early stages it may be limited to one finger or thumb, then gradually spreads to involve the entire upper extremity, the lower extremity of the same side and then usually involves the other side of the body. It may, however, remain unilateral for a number of months or longer. The tremor is present during rest and ceases or diminishes during an action. An occasional patient can control the tremor voluntarily but in such a case, as in a tic, the tremor may then be exaggerated temporarily. The characteristic tremor is the pill rolling one, but flexion and extension of the wrist and fingers or pronation and supination of the forearm are common without a definite pill rolling element. The tremor may involve the head, jaw and occasionally the tongue. Like practically all irregular movements it disappears during sleep. The tremor may be imparted to the handwriting and the tremor plus rigidity produce a progressive smallness of the handwriting which is characteristic of the disease.

*Objective Signs.*—Although there are types of paralysis agitans in which rigidity is marked and the tremor slight or absent (the so-called *paralysis agitans sine agitatione*) the rigidity usually follows the tremor. When the extremities are passively moved a wax like resistance occurs, the cogwheel symptom. Rigidity of the face causes the masked expression, the bodily attitude is that of the position of an old bent man, the trunk flexed, head flexed and slight flexion of the upper extremities and at the knees. The hand may assume various positions, the flipper hand being not uncommon. The thumb may be held in the palm of the hand and the fingers flexed over it. Because of the rigidity all voluntary movement is slowly initiated and slowly carried out. A common sign early in the disease is the inability to approximate and separate rapidly the thumb and forefinger on at least one side. Change

tary weeping is mistaken for manic depressive insanity in the depressed phase

The *outlook* in cases of pseudobulbar palsy is poor Some of these patients choke to death or develop pneumonia due to the difficulty in swallowing so that special care is necessary as far as feeding is concerned

### Myasthenia Gravis

*Asthenic bulbar paralysis* also referred to as *bulbar palsy without anatomic findings* is a relatively uncommon disease of the muscular system and is without definite neuropathologic changes The endocrine system may be at fault In many cases an enlarged persistent thymus or a lymphoid tumor of the thymus gland has been found at necropsy The muscles most frequently affected are those of the eyes face and tongue, throat and neck although all the muscles of the body may be involved and sudden death probably from involvement of the myocardium has been reported The muscles may be infiltrated with round cells Recent studies indicate that myasthenia is primarily a disorder of the myoneural junction Ordinarily the transmission of nerve impulses at the myoneural junction depends on the liberation of acetylcholine In myasthenia there is either a deficient liberation of acetylcholine or else acetylcholine is rapidly destroyed by cholinesterase Prostigmine inhibits cholinesterase activity while quinine increases it

The most important *symptom* of myasthenia gravis is weakness or paralysis of the muscles brought on by use and relieved by rest As mentioned before the muscles most usually affected are those of the eyes resulting in ptosis and diplopia of the lips tongue, pharynx and jaw resulting in dysarthria dysphagia and difficulty in chewing and of the muscles of the neck resulting in difficulty in holding the head erect In occasional cases the muscles of the trunk and extremities may also be involved To elicit the symptoms it is only necessary to have the patient perform some given muscular effort a number of times When the muscles become fatigued movement is no longer possible The same thing in a way is accomplished by stimulating the muscles with faradic current After a number of stimulations the muscle reacts feebly and finally fails to respond, after a rest the excitability returns (Jolly reaction) The disease is more frequently seen between the ages of twenty and fifty years females are more often involved than males Remissions are common Sensory loss atrophy fibrillations and the reversal of the electrical reactions do not occur Remissions often occur during pregnancy The outlook is bad for recovery

The *diagnosis* is to be made from bulbar palsy encephalitis hysteria tumors of the bulb cerebral syphilis and tumors of the corpora quadrigemina There is no entirely successful *treatment* of the disease The patient should be placed at rest and fatigue avoided The diet should be soft and liquid Tonics ephedrine sulphate and pilocarpine and epinephrine *are* recommended Prostigmine has given valuable aid both in the diagnosis and treatment of the disease An injection of the drug causes a rapid and usually complete disappearance of the symptoms whereas other conditions do not respond The drug should be used hypodermically for quick results and as a therapeutic test Prostigmine can also be given by mouth 15 mg every two to four hours The dosage must be individualized In many patients after prolonged administration the drug becomes progressively less effective Ephedrine augments the effect of prostigmine There have been reports of improvement following thymectomy especially when a thymic tumor is found

### WERNICKE S POLIOENCEPHALITIS

Polioencephalitis hemorrhagica superior of Wernicke occurs in association with chronic alcoholism hyperemesis gravidarum gastric carcinoma and other conditions in which there may be a disturbance of nutrition The disease is probably due to vitamin deficiency particularly of thiamin The pathologic changes consist of petechial hemorrhages vascular proliferation and mild nerve cell damage in the periaqueductal region the mammillary bodies the walls of the third ventricle and the gray matter of the floor of the fourth ventricle Clinically it is characterized by headache, dizziness vomiting

comes in contact should be agreeable kindly and optimistic He should avoid excitement and excessive physical exertion Hydrotherapy mild massage passive movement and exercises within reason are indicated Sometimes mild electricity seems to improve the sufferer from paralysis agitans largely because of its psychic effect From the drug standpoint a combination of bromide and hyoscine does most to relieve the tremor The dose of these drugs should be small at first and gradually increased In some cases tincture of stramonium has a beneficial effect upon the tremor New drugs such as artane, panparnit tolserol and benadryl have recently been introduced but so far have produced no dramatic beneficial results Sleeplessness pain and distress in the extremities caused by tremor and rigidity call for the use of hypnotics and analgesics In the patient with advanced paralysis agitans who suffers intensely it is as justifiable to prescribe opium in some form as it is to do so for cancer The use of such drugs as tobacco coffee tea and alcohol are capable of producing tremor and should be forbidden Phenobarbital and allied drugs make the patient worse Dexedrine and Benzedrine apparently has a beneficial effect in respect to relief of tension and relieving the depressive symptoms

Various operative procedures such as cutting the pyramidal tracts and ablation of the premotor cortex have been advocated In our experience they have produced no good results and at present must be regarded as experimental

## SYDENHAM S CHOREA

*Synonyms* —St Vitus dance Acute chorea

For years Sydenham s chorea was thought to be a functional nervous disorder but it is now *considered* an infectious disease closely allied to rheumatic fever It has no relation to epidemic encephalitis which however has a choreiform type A mental shock or trauma sometimes seems to bring on the disease certainly they exaggerate the condition if already present The disease has a tendency to be complicated by endocarditis polyarthritis and tonsillitis The pathology of Sydenham s chorea is not on a firm basis although it is assumed that changes in the corpus striatum are responsible for the choreiform movements The brain may be hyperemic and occasionally if a case is complicated by endocarditis emboli may occur Eosinophilia is frequently found

The disease is one which occurs particularly between the ages of five and fifteen years, and girls are more susceptible than boys The disease is *more frequent* in February and March and in October and November Heredity has nothing to do with the onset of the acute chorea and hereditary chorea and Sydenham s chorea have no relation as far as etiology is concerned It is more common in races which are temperamental, and also is seen more frequently in children who are in a low state *of general health Pregnancy predisposes to Sydenham s chorea* and relapses of chorea are especially common during pregnancy The first pregnancy is more likely to be complicated by chorea than later ones

*Symptoms* —The disease usually appears gradually The child is out of sorts and suffers from headache anorexia and a general slowing up The temperature may be slightly *elevated during the early* stages of chorea The choreiform movements may be localized to one side of the body or to one extremity or they may be generalized The movements are slow and purposeless never rhythmical and as far as rapidity is concerned are midway between athetosis and tic Like practically all spontaneous movements they cease during sleep *though in some cases they may be so* severe as to prevent sleep Any movement which the patient attempts will be affected if the part used is choreic Throughout the disease for example the patient suffering with acute chorea has difficulty in feeding himself and frequently drops dishes The child has a tendency in performing an act to overdo it At first one side may be affected more than the other and in rare cases chorea may be confined to one side but as a rule both sides of the body are irregularly affected as the disease progresses Involvement of the muscles of speech is common and in severe cases the speech is extremely dysarthric When the choreiform

of position is difficult and often impossible The common maneuver in getting up is for the nurse to grasp both hands of the patient and slowly pull him to a standing position A common complaint in patients with paralysis agitans is their inability to turn over in bed many of them if they desire to change their position must get out of bed and then re-enter it The winking reflex is usually affected An involuntary step backward or to either side as the patient arises from a sitting position is a common symptom and may be among the earliest These signs are referred to as retropulsion and lateropulsion The most characteristic thing as the patient walks is the loss of the automatic swinging movements of the arms the foot drags and shuffles Another characteristic of the gait usually not seen until the disease has advanced is *festination* In this condition the patient starts off slowly and then the rate of progression becomes more rapid until he is running and the body is bent forward Although it would seem as though he must fall he rarely does so He stops himself by grasping hold of a person or an object in his path

The various emotions are rarely transmitted to the facial expression although a wan ghost like smile occasionally occurs Anger or displeasure may cause flushing of the face The loss of movement which occurs is not a paralysis in the ordinary sense of the word but is more an inhibition of motion due to rigidity which may become so pronounced that the patient has practically no voluntary movement left except in the eyes Reflex acts such as swallowing are not affected if at all until late in the disease and the sphincters usually remain intact Speech often a monotone may develop a sort of festination and as the disease progresses the patient may become completely anarthric The deep reflexes are normal or slightly hyperactive but if much rigidity is present they may be difficult to obtain The superficial reflexes are normal Babinski s sign does not occur in the ordinary case of paralysis agitans

Sensation objectively tested is not involved Pain is not an infrequent symptom in paralysis agitans, especially in the upper extremities It is probably due to the muscular rigidity and pull on the joints A burning sensation is not uncommon and flushing and excessive sweating are frequently seen Patients with paralysis agitans often stand the cold much better than the hot weather and some of them are much better when they wear light clothing Salivation a common symptom in the Parkinsonism due to epidemic encephalitis is not so frequently seen in the ordinary type of the disease The mentality of patients suffering from paralysis agitans is not altered although they are often fussy irritable and unreasonable They are more subject to depression than the normal person, and also more likely to develop a real psychosis which is usually of a depressive suspicious nature

*Diagnosis* —In the early stage of the disease when the tremor is slight neuralgic pains present and nothing found to account for them the patient suffering from Parkinsonism may be thought to be psychoneurotic The tremor of paralysis agitans will disappear on the paralyzed side if the patient has an attack of cerebral thrombosis The tremor of senility will probably offer the greatest difficulty in differentiation This tremor affects chiefly the head and upper extremities and is increased during action The so-called rabbit tremor or jaw tremor is more characteristic in the senile case Multiple sclerosis and other forms of irregular movement such as chorea and athetosis should not be difficult to differentiate It is often difficult to say whether a patient suffering from paralysis agitans is a victim of the degenerative type of the disease or whether he has Parkinsonism due to chronic encephalitis The distinction will be particularly difficult in those cases of chronic encephalitis where there is no history of an acute infection

The *prognosis* in paralysis agitans is unfavorable for recovery The outlook for life is good the patient often living from five to twenty years The duration depends largely upon the age of onset

*Treatment* —No known treatment is curative however much can be done to help the patient and to relieve his suffering He should be placed in the best possible state of general health he should have pleasant surroundings and the people with whom he

comes in contact should be agreeable kindly and optimistic He should avoid excitement and excessive physical exertion Hydrotherapy mild massage passive movement and exercises within reason are indicated Sometimes mild electricity seems to improve the sufferer from paralysis agitans largely *because of its psychic effect From the drug* standpoint a combination of bromide and hyoscine does most to relieve the tremor The dose of these drugs should be small at first and gradually increased In some cases tincture of stramonium has a beneficial effect upon the tremor New drugs such as artane, panparnit tolserol and benadryl have recently been introduced but so far have produced no dramatic beneficial results Sleeplessness pain and distress in the extremities caused by tremor and rigidity call for the use of hypnotics and analgesics *In the patient with advanced paralysis* agitans who suffers intensely it is as justifiable to prescribe opium in some form as it is to do so for cancer The use of such drugs as tobacco coffee tea and alcohol are capable of producing tremor and should be forbidden Phenobarbital and allied drugs make the patient worse Dexedrine and Benzedrine apparently has a beneficial effect in respect to relief of tension and relieving the depressive symptoms

*Various operative procedures such as cut*ting the pyramidal tracts and ablation of the premotor cortex have been advocated In our experience they have produced no good results and at present must be regarded as experimental

## SYDENHAM'S CHOREA

*Synonyms* —St Vitus dance Acute chorea

For years Sydenham's chorea was thought to be a functional nervous disorder but it is now considered an infectious disease closely allied to rheumatic fever It has no relation to epidemic encephalitis which however has a choreiform type A mental shock or trauma sometimes seems to bring on the disease *certainly they exaggerate the condi*tion if already present The disease has a tendency to be complicated by endocarditis polyarthritis and tonsillitis The pathology of Sydenham's chorea is not on a firm basis, although it is assumed that changes in the corpus striatum are responsible for the choreiform movements The brain may be hyperemic and occasionally if a case is *complicated by endocarditis emboli may* occur Eosinophilia is frequently found

The disease is one which occurs particularly between the ages of five and fifteen years and girls are more susceptible than boys The disease is more frequent in February and March and in October and November Heredity has nothing to do with the onset of the acute chorea and hereditary chorea and Sydenham's chorea have no relation as far as etiology is concerned It is more common in races which are temperamental, and also is seen more *frequently in children who are in a low state* of general health Pregnancy predisposes to *Sydenham's chorea* and relapses of chorea are especially common during pregnancy The first pregnancy is more likely to be complicated by chorea than later ones

*Symptoms* —The disease usually appears gradually The child is out of sorts and suffers from headache anorexia and a general slowing up The temperature may be slightly elevated during the early stages of chorea The choreiform movements may be localized to one side of the body *or to one extremity or they may be gen*eralized The movements are slow and purposeless never rhythmical and as far as rapidity is concerned are midway between athetosis and tic Like practically all spontaneous movements they cease during sleep though in some cases they may be so severe as to prevent sleep Any movement which the patient attempts will be affected if the part used is choreic Throughout the disease for example the patient suffering with acute chorea has difficulty in feeding himself and frequently drops dishes The child has a tendency in performing an act to overdo it At first one side may be affected more than the other and in rare cases chorea may be confined to one side, but as a rule both sides of the body are irregularly affected as the disease progresses Involvement of the muscles of speech is common and *in severe cases the speech is* extremely dysarthric When the choreiform

movements affect the face *grimacing* results and involvement of the tongue produces disturbance of speech and chewing. Due to the irregular movements and the incoordination which results, weakness of the *affected* extremities may be present and may be so pronounced as to produce the so called paralytic type of the disease. While pyramidal tract signs may be seen they certainly are extremely rare. It is quite common in any form of chorea for the great toe to extend as a manifestation of chorea *if the plantar surface is stimulated just as this* choreiform movement occurs, the patient may be thought to have a Babinski sign. Inasmuch as the state of the deep reflexes varies there is nothing characteristic about *them*. Excitement and fatigue increase the movements. The pupils and ocular nerves electrical reactions and sensation are normal. Pain may occur in the extremities especially if the movements are severe or if the individual has arthritis. The patient suffering from Sydenham's chorea is irritable dull and shows a general *reduction in his mental* faculties. A toxic exhaustive psychosis may ensue, with excitement visual and auditory hallucinations and delusions. Cases of chorea complicating pregnancy are especially liable to develop *mental symptoms* (chorea insaniens). Evidence of tonsillitis arthritis and endocarditis may be found. The average duration of Sydenham's chorea is two or three months the extremes being six weeks to eight months. *Occasionally a more* or less chronic state may ensue.

The greatest mistake in *diagnosis* is in calling cases of tic or habit spasm chorea. The tic or habit spasm is quick apparently purposeful usually limited to certain groups of muscles and does not vary from week to week. They are especially likely to involve the face head or shoulders. Choreiform and choreo athetoid movements may occur in the acute stage of epidemic encephalitis or may be a manifestation of chronic encephalitis. The *movements* appear much more rapidly in encephalitis as a rule they are more marked and are accompanied by other signs especially ocular palsies. *Hysteria may be* mistaken for chorea especially in pregnancy. The irregular *movements* which occur in hysteria are usually not distinctly chorei form but are more tic like in character. Furthermore, the patient usually responds quickly to isolation and *psychotherapy*.

The *prognosis* for recovery is excellent, an occasional patient dies but rarely does the disease become chronic. The death rate in chorea complicated by pregnancy has been *estimated as high as 20 per cent, but this* figure is probably too high. If endocarditis occurs signs of that affection will persist.

*Treatment*.—The most important consideration is rest in bed which should be continued until the movements have disappeared. The patient should be placed in the sunniest and best ventilated room in the house and visitors excluded. Stimulating games and reading should not be permitted. In view of the fact that many of the children are underweight and undernourished a *high caloric high vitamin diet rich in greens* and fruit should be ordered. Hydrotherapy, especially a continuous warm tub if available decreases the choreiform movements as do also warm packs or an ordinary warm bath. *The drugs found most efficacious are* bromides and salicylates. Barbituric preparations may be used for their hypnotic and sedative effects. Nonspecific protein therapy such as typhoid vaccine and the in*duction of fever by the hypertherm have* been recommended. The writers have seen excellent results in which the course of the disease was cut short by short courses of fever therapy. Particular attention should *be paid to the general health of the patient* he should be given plenty of fresh air and sunshine bad teeth and tonsils should be removed and other infections such as pyelitis cleared up. If endocarditis has occurred *the child should be kept in bed for a longer* period of time. After the movements have ceased the child may be gotten out of bed by easy stages permitting him to go downstairs and then out of the house. It will *usually not be necessary to employ physiotherapy* although occasionally massage may be beneficial. Stimulating physiotherapeutic treatment such as electricity should not be used.

## HUNTINGTON'S CHOREA

Hereditary chorea begins about the age of thirty five or forty years usually involves

more than one member of a family and the history of its occurrence in the family may date back many years On the other hand occasional cases of Huntington's chorea are seen in which the family occurrence of the disease is absent The main facts on which the diagnosis is based are heredity choreiform movements and dementia The choreiform movement as a rule begins in one hand or in the face and then gradually spreads to involve the entire body The irregular movements do not differ from those of Sydenham's chorea When the disease is far advanced it is necessary to confine the patient to a wheel chair or bed because the violence of the movements causes falls and injuries Movements of the face produce *grimacing and those of the trunk pelvis* and lower extremities produce a bizarre disordered gait the patient dipping and swaying forward backward and to either side Mentally the patient deteriorates and if he lives long enough suffers from complete dementia

In the early stages he may show ideas of persecution and get into legal difficulties because of poor judgment and loss of memory As in most hereditary diseases males are affected more than females In a family in which this disease exists there may be instances of chorea without dementia mental disease without chorea and some *instances in which neither distinct mental* disease nor chorea is found but some members of the *family however are queer* and eccentric

Huntington's chorea has no relation to Sydenham's chorea and rheumatic infections The underlying *pathology* of Huntington's chorea is an atrophy of the motor cells of the corpus striatum and also atrophy of the frontal cortex At times changes suggestive of encephalitis are found in the brain The disease is progressive incurable and may last from one to fifteen years or more *Huntington's chorea may be confused with* other forms of chorea produced by changes in the basal ganglia

The *treatment* is ineffectual but for a time the chorea may be controlled by sedatives such as bromide hyoscine and stramonium It is practically always necessary with time to institutionalize the patient Marriage of members of families in which the disease exists should be discouraged

## PROGRESSIVE LENTICULAR DEGENERATION

A description of progressive lenticular degeneration by Wilson in 1912 focused attention on the basal ganglia Wilson's disease is a familial condition appearing as a rule before the age of thirty years and complicated by a hob-nail cirrhosis of the liver It is characterized by a rhythmic tremor of the extremities sometimes of the paralysis agitans type although occasionally *choreiform or athetoid movements are seen* The tremor unlike that of paralysis agitans *is increased by action The extremities* and face are hypertonic the hypertonicity of the muscles of the face producing a spastic smile Involuntary emotionalism especially of laughter is commonly seen Because of the hypertonicity of the extremities contractures develop The deep reflexes are usually hyperactive but positive signs of pyramidal tract disease are lacking True paralysis is not present but the scope of movement is greatly limited because of tremor and rigidity The pupils cranial nerves abdominal reflexes and sensation are normal The involvement of the muscles of speech and swallowing produce dysarthria *and dysphagia The disease is progressive* incurable and fatal as a rule under ten years

In addition to hob-nail cirrhosis of the liver *postmortem examination* reveals degeneration of the lenticular nuclei most marked in the putamen and to a less degree in the globus pallidus The degeneration sometimes ends in cavitation

### PSEUDOSCLEROSIS

The syndrome of pseudosclerosis is similar *in many respects* to Wilson's disease and by many Wilson's disease and pseudosclerosis are considered *varieties of the same* condition Cirrhosis of the liver is found in both although more frequently in Wilson's disease Enlargement of the spleen is sometimes found in pseudosclerosis Tremor especially an intention tremor is commonly

seen in pseudosclerosis and rigidity is usually absent In pseudosclerosis a peculiar greenish discoloration of the corneal margins is frequently observed This has been called the Kayser-Fleischer ring or Fleischer-Strumpell ring The speech and type of tremor may suggest multiple sclerosis but nystagmus optic atrophy, *pyramidal tract signs and* alteration of the colloidal gold curve test are absent

## EPIDEMIC ENCEPHALITIS

The condition which we now commonly refer to as epidemic encephalitis was first described by von Economo under the title of *lethargic encephalitis* There is much in medical history to indicate that the disease has been prevalent in the past and has been described under various titles After its appearance in Europe, in 1917, the disease spread over the entire world The first cases in the United States occurred toward the end of 1918 and the early part of 1919 The first great epidemic of encephalitis came after the severe and widespread epidemic of influenza The type of the disease varied in *different years* It is not contagious in the ordinary sense of the word and while more than one case has occurred in a family even this is *uncommon The writers have never* seen a case develop in a hospital ward either among other patients or among the doctors and *nurses handling cases of epi*demic encephalitis

*Pathogenesis* —The cause of the disease is supposed to be a *filtrable virus Whether* there is a relation between encephalitis and influenza or encephalitis and poliomyelitis and epidemic meningitis is not known There is much evidence to associate herpes febrilis and encephalitis and also perhaps chickenpox The infection probably enters through the naso pharynx and the incubation period is about ten days

*Pathology* —The brunt of the disease is borne by the region of the aqueduct of Sylvius, the basal ganglia the pons and medulla and substantia nigra While the cortex and spinal cord may be involved the disease has a predilection for the parts mentioned The meninges usually show a mild to moderate inflammatory reaction

*Microscopically* the chief feature is a perivascular infiltration with lymph or round cells In the subacute and chronic cases of encephalitis changes are found, especially in the *corpus striatum thalamus, in the* hypothalamic structures and in the substantia nigra Changes in other parts of the *nervous system may* be discovered, but are uncommon The vessel walls often show degeneration and pseudocalcareous deposits

*Symptoms* —The disease involves the sexes about equally and, while it occurs at any age, young adults are more frequently involved Many types of the disease have been described as far as symptomatology is concerned, and the various types mean nothing more nor less than that different parts of the nervous system are affected by the virus The symptomatology varies in different years The most common symptoms are headache, lethargy and diplopia The temperature is elevated as a rule, but does not often go above 101° to 102° F The lethargy varies from a slight stupor to a profound coma Quite often even in the deepest stupor the patient may be aroused He will then carry out a command or two and *drop back to sleep The ocular palsies* present in the disease are due to the inflammatory reactions in or near the nuclei of *these nerves The ocular palsies* either persist or clear up and other cranial nuclei may be involved especially the seventh *Therefore a bilateral facial palsy giving an* expressionless appearance to the face is seen An acute bulbar palsy is occasionally a manifestation of *epidemic encephalitis There* is no other disease which produces an irregular succession of cranial nerve paralyses in the course of a few hours or a few days and quite often as a fresh involvement occurs the nerves first involved clear up Nuchal rigidity and Kernig s sign are frequently seen in the acute stage of epidemic encephalitis and in the first two or three years in which the disease became *prevalent* often led to the erroneous diagnosis of meningitis especially tuberculous Involvement of the *bulb produces dangerous* symptoms often with irregularity of the pulse and respiration and is a common cause of death which may *occur suddenly* Catatonia occasionally is seen This symptom may

lead to mistakes in diagnosis such as hysteria or dementia precox The deep reflexes are frequently unaltered, and Babinski s sign a great rarity *Involvement of the sphincters* does not usually occur but incontinence of urine is occasionally seen probably due to the stupor of the patient Impairment of *accommodation and loss of pupillary re*action are frequently seen in the acute stage A paralysis agitans syndrome, coming on acutely is occasionally encountered Radicular pains myoclonic movements in various parts of the body especially in the abdominal muscles are common symptoms In some patients particularly in children insomnia rather than lethargy occurs and a reversal of the sleep formula is seen Hiccough may be a prominent symptom

The leukocytes in the blood are usually slightly to moderately increased The number of cells in the *spinal fluid* varies In some cases the count is practically normal and in others it goes as high as 400 Thirty to forty cells is a common finding The cells are usually lymphocytes The most important finding in the spinal fluid is the increase in the sugar content The protein is also increased and not infrequently an alteration in the colloidal gold curve in the middle zone is found The urine often shows signs of nephritis which is in a few cases a contributing cause of death Delirium excitement maniacal states and one suggestive of Korsakoff s psychosis may be seen Herpes is an uncommon complication of epidemic encephalitis Slight optic neuritis may be seen There are undoubtedly many mild and abortive types of the disease just as there are of acute anterior poliomyelitis The disease has not been pandemic since 1926 although isolated epidemics have occurred since that time neither the clinical course nor the pathology were similar to the disease as originally described

*Diagnosis* —In view of the signs of meningitis the most common mistake in diagnosis is in assuming that tuberculous or some other form of meningitis is present The greatest help in differentiating these two conditions is in the examination of the spinal fluid

It is often extremely difficult to distinguish between acute multiple sclerosis and acute disseminated encephalomyelitis from epidemic encephalitis in fact some instances *of acute disseminated encephalomyelitis may* be due to the virus of encephalitis The presence of definite pyramidal tract signs will usually point to these conditions rather than to epidemic encephalitis Neurosyphilis especially if producing lethargy and cranial nerve palsies often presents a problem in differential diagnosis Occasionally a patient under treatment for neurosyphilis develops epidemic encephalitis Cerebral neoplasm often presents difficulties in differential diagnosis Uremia and diabetes can usually be distinguished by a complete survey of the case

*Prognosis* —The mortality varies from 5 to 25 per cent The duration of the acute symptoms varies from a few hours to a *number of months The longer the patient* has remained ill at the onset, the more likelihood there is that he will develop evidence of chronic encephalitis This is not however, a constant rule The most foreboding thing that happens in the course of the illness is signs of bulbar paralysis, frequently resulting in sudden death Many patients never make a complete recovery, but immediately develop signs of Parkinsonism or other evidences of chronic encephalitis Depending on the predominance of symptoms types of the diseases are classified as lethargic, hyperkinetic myostatic meningitic psychotic bulbar myelitic and neuritic

The percentage of cases which develop *signs of chronic encephalitis* is high The commonest syndrome of chronic encephalitis is Parkinsonism which may begin during the acute illness or which may not appear for years afterward Various types of irregular movement such as chorea athetosis facial tic or spasms are occasionally symptoms of the chronic stage of the disease The pupils not infrequently are irregular unequal and either dilated or contracted Loss of accommodation and at times an Argyll Robertson pupil may be observed So-called oculogyric crises in which the eyeballs *become fixed in one* position for a few minutes to hours are very disturbing symptoms in the chronic stage Tachypnea

seen in pseudosclerosis and rigidity is usually absent In pseudosclerosis a peculiar greenish discoloration of the corneal margins is frequently observed This has been called the Kayser Fleischer ring or Fleischer-Strumpell ring The speech and type of tremor may suggest multiple sclerosis but nystagmus optic atrophy pyramidal tract signs and alteration of the colloidal gold curve test are absent

## EPIDEMIC ENCEPHALITIS

The condition which we now commonly refer to as epidemic encephalitis was first described by von Economo under the title of *lethargic encephalitis* There is much in medical history to indicate that the disease has been prevalent in the past and has been described under various titles After its appearance in Europe, in 1917, the disease spread over the entire world The first cases in the United States occurred toward the end of 1918 and the early part of 1919 The first great epidemic of encephalitis came after the severe and widespread epidemic of influenza The type of the disease varied in different years It is not contagious in the ordinary sense of the word and while more than one case has occurred in a family even this is uncommon The writers have never seen a case develop in a hospital ward either among other patients or among the doctors and nurses handling cases of epidemic encephalitis

*Pathogenesis* —The cause of the disease is supposed to be a filtrable virus Whether there is a relation between encephalitis and influenza or encephalitis and poliomyelitis and epidemic meningitis is not known There is much evidence to associate herpes febrilis and encephalitis and also perhaps chickenpox The infection probably enters through the naso pharynx and the incubation period is about ten days

*Pathology* —The brunt of the disease is borne by the region of the aqueduct of Sylvius, the basal ganglia the pons and medulla and substantia nigra While the cortex and spinal cord may be involved the disease has a predilection for the parts mentioned The meninges usually show a mild to moderate inflammatory reaction *Microscopically* the chief feature is a perivascular infiltration with lymph or round cells In the subacute and chronic cases of encephalitis changes are found, especially in the corpus striatum thalamus in the hypothalamic structures and in the substantia nigra Changes in other parts of the nervous system may be discovered, but are uncommon The vessel walls often show degeneration and pseudocalcareous deposits

*Symptoms* —The disease involves the sexes about equally and while it occurs at any age, young adults are more frequently involved Many types of the disease have been described as far as symptomatology is concerned and the various types mean nothing more nor less than that different parts of the nervous system are affected by the virus The symptomatology varies in different years The most common symptoms are headache lethargy and diplopia The temperature is elevated as a rule but does not often go above 101° to 102 F The lethargy varies from a slight stupor to a profound coma Quite often even in the deepest stupor the patient may be aroused He will then carry out a command or two and drop back to sleep The ocular palsies present in the disease are due to the inflammatory reactions in or near the nuclei of these nerves The ocular palsies either persist or clear up and other cranial nuclei may be involved especially the seventh Therefore a bilateral facial palsy giving an expressionless appearance to the face is seen An acute bulbar palsy is occasionally a manifestation of epidemic encephalitis There is no other disease which produces an irregular succession of cranial nerve paralyses in the course of a few hours or a few days and quite often as a fresh involvement occurs the nerves first involved clear up Nuchal rigidity and Kernig s sign are frequently seen in the acute stage of epidemic encephalitis and in the first two or three years in which the disease became prevalent often led to the erroneous diagnosis of meningitis especially tuberculous Involvement of the bulb produces dangerous symptoms often with irregularity of the pulse and respiration and is a common cause of death which may occur suddenly *Catatonia* occasionally is seen This symptom may

lead to mistakes in diagnosis such as hysteria or dementia praecox. The deep reflexes are frequently unaltered and Babinski's sign a great rarity. Involvement of the sphincters does not usually occur, but incontinence of urine is occasionally seen probably due to the stupor of the patient. Impairment of accommodation and loss of pupillary reaction are frequently seen in the acute stage. A paralysis agitans syndrome coming on acutely is occasionally encountered. Radicular pains, myoclonic movements in various parts of the body especially in the abdominal muscles, are common symptoms. In some patients particularly in children insomnia rather than lethargy occurs and a reversal of the sleep formula is seen. Hiccough may be a prominent symptom.

The leukocytes in the blood are usually slightly to moderately increased. The number of cells in the *spinal fluid* varies. In some cases the count is practically normal and in others it goes as high as 400. Thirty to forty cells is a common finding. The cells are usually lymphocytes. The most important finding in the spinal fluid is the increase in the sugar content. The protein is also increased and not infrequently an alteration in the colloidal gold curve in the middle zone is found. The urine often shows signs of nephritis which is in a few cases a contributing cause of death. Delirium excitement maniacal states and one suggestive of Korsakoff's psychosis may be seen. Herpes is an uncommon complication of epidemic encephalitis. Slight optic neuritis may be seen. There are undoubtedly many mild and abortive types of the disease just as there are of acute anterior poliomyelitis. The disease has not been pandemic since 1926 although isolated epidemics have occurred since that time neither the clinical course nor the pathology were similar to the disease as originally described.

*Diagnosis*—In view of the signs of meningitis the most common mistake in diagnosis is in assuming that tuberculous or some other form of meningitis is present. The greatest help in differentiating these two conditions is in the examination of the spinal fluid.

It is often extremely difficult to distinguish between acute multiple sclerosis and acute disseminated encephalomyelitis from epidemic encephalitis in fact some instances of acute disseminated encephalomyelitis may be due to the virus of encephalitis. The presence of definite pyramidal tract signs will usually point to these conditions rather than to epidemic encephalitis. Neurosyphilis especially if producing lethargy and cranial nerve palsies often presents a problem in differential diagnosis. Occasionally a patient under treatment for neurosyphilis develops epidemic encephalitis. Cerebral neoplasm often presents difficulties in differential diagnosis. Uremia and diabetes can usually be distinguished by a complete survey of the case.

*Prognosis*—The mortality varies from 5 to 25 per cent. The duration of the acute symptoms varies from a few hours to a number of months. The longer the patient has remained ill at the onset the more likelihood there is that he will develop evidence of chronic encephalitis. This is not however a constant rule. The most foreboding thing that happens in the course of the illness is signs of bulbar paralysis, frequently resulting in sudden death. Many patients never make a complete recovery but immediately develop signs of Parkinsonism or other evidences of chronic encephalitis. Depending on the predominance of symptoms types of the diseases are classified as lethargic hyperkinetic myostatic meningitic, psychotic bulbar myelitic and neuritic.

The percentage of cases which develop signs of *chronic encephalitis* is high. The commonest syndrome of chronic encephalitis is Parkinsonism which may begin during the acute illness or which may not appear for years afterward. Various types of irregular movement such as chorea athetosis facial tic or spasms are occasionally symptoms of the chronic stage of the disease. The pupils not infrequently are irregular unequal and either dilated or contracted. Loss of accommodation and at times an Argyll Robertson pupil may be observed. So-called oculogyric crises in which the eyeballs become fixed in one position for a few minutes to hours are very disturbing symptoms in the chronic stage. Tachypnea

with signs of hyperventilation are rare manifestations of chronic encephalitis. Behavior disorders and reversal of the sleep formula are known sequels especially in children. Narcolepsy, in many instances is due to chronic encephalitis. Symptoms very suggestive of a psychoneurosis frequently exist for months or years before the patient develops signs, which make it possible to say that the disease is definitely organic and of an encephalitic nature.

*Treatment.*—There is no specific in the treatment of this disease which is largely symptomatic. As yet none of the presently available antibiotics has proved to be of any established value.

## ENCEPHALITIS DUE TO NEUROTROPIC VIRUSES

The encephalitides due to specific viruses possessing a selective affinity for the central nervous system include St Louis encephalitis, Japanese B encephalitis, Eastern and Western equine encephalomyelitis, Venezuela encephalitis, Australian X disease, Russian forest-spring encephalitis and West Nile encephalitis. Although the viruses producing these diseases show certain antigenic relationships and their clinical and pathologic manifestations are often similar they are immunologically distinct. The epidemiology of these virus forms of encephalitis has not as yet been definitely established but the available evidence suggests a widespread animal host reservoir with arthopods such as mosquitoes and ticks as transmission vectors. Sporadic epidemics of the St Louis and equine encephalomyelitis types have been prevalent in the United States particularly in the Western regions.

## ST LOUIS ENCEPHALITIS

From July to October 1933 an epidemic of slightly more than 1000 cases of encephalitis occurred in the St Louis area. The causative agent was found to be a virus pathogenic for mice and monkeys as well as man which was neutralized by the serum of patients convalescing from the disease. The seasonal incidence suggested that the spread of the contagion might be by an insect vector but attempts to reproduce the disease in monkeys and man by mosquitoes presumably infected, were unsuccessful. As yet the exact mode of transmission is not known. Individual susceptibility rather than exposure to infection appears to be the principal factor in determining morbidity.

In the St Louis epidemic, the highest incidence and mortality occurred in the older age groups. The incubation period varied from four to twenty one days. Clinically, the disease was characterized by an abrupt onset of high fever, headache, meningeal signs, mental confusion, drowsiness and other neurologic manifestations such as tremors, speech defects and reflex alterations. Ocular manifestations were very rare. In some cases there was a prodromal period of malaise, chills, "grippe" like pains in the back and neck, nausea, vomiting and abdominal discomfort. Following a stormy course in most cases the temperature fell by lysis within seven to ten days and led to complete recovery in two to three weeks. The majority of deaths occurred within the first week. The mortality was about 20 per cent. Residual sequels so common following the epidemic type of encephalitis were very rare.

The blood count usually revealed a moderate polymorphonuclear leukocytosis (12 000 to 20 000). The spinal fluid was clear but often under slightly increased pressure with an increase in cells (average 50 to 250, lymphocytes predominating). The spinal fluid sugar was normal or slightly increased and the globulin moderately increased.

The essential pathologic findings were severe vascular congestion with occasional petechial hemorrhages, cellular infiltration with monocytes and varying degrees of degenerative neuronal changes. The inflammatory foci were widespread, frequently occurred in the cortex and were not limited to the mid brain or basal ganglia.

Symptoms similar to those of the St Louis epidemic were found in the 1941 epidemic prevalent in the Dakotas, Minnesota, Montana and Nebraska.

## JAPANESE B ENCEPHALITIS

This disease occurs only in Japan and clinically is similar to the St Louis type but differs serologically. The virus is probably transmitted by mosquitoes although the host animal reservoirs are not known.

## EQUINE ENCEPHALOMYELITIS

In 1932, 3 cases of encephalitis occurring in men who had worked in close contact with sick horses during an epizootic of equine encephalitis were reported from California. Although the disease occurred in epizootic form in widespread areas of the United States during the subsequent years no further human cases were recognized until the summer of 1938 when minor epidemics closely coinciding with the appearance of epizootic in the respective region occurred in Southern California, Minnesota, Wisconsin, Southeastern Massachusetts and Rhode Island. The etiologic agent proved to be a virus of which two immunologically distinct types, the Eastern and Western, were recognized. The virus reservoirs are possibly birds and insects. It has been demonstrated that the virus can be transmitted by mosquitoes (Aedes aegypti).

The common clinical features are an abrupt onset of headache, malaise and nausea with fever (100° to 104°) and drowsiness. Meningeal

signs convulsions, stupor respiratory failure and death develop rapidly Some cases show a transient remission with a more severe recrudescence of symptoms seven to ten days later The average duration of illness was seven days The Eastern form is much more severe than the Western, the mortality in the former being 75 per cent against 5 per cent in the latter In the Massachusetts epidemic 70 per cent of cases occurred in children Sequels in the form of mental retardation hemiparesis aphasia and emotional instability are frequent following the Eastern form but rare following the Western

The blood count usually shows a polymorphonuclear leukocytosis (10 000 to 60 000) The spinal fluid pressure is normal or slightly increased with a cell count of 500 to 1000 usually polymorphs The spinal fluid protein is increased

Pathologically the disease is characterized by perivascular cell infiltration with extreme degenerative changes in the neurones

## VENEZUELAN ENCEPHALITIS

A disease clinically similar but immunologically distinct from equine encephalomyelitis is reported to have occurred in Venezuela in 1938

## AUSTRALIAN X DISEASE

This type of encephalitis occurred as an epidemic in children in New South Wales in 1917 1918, 1922 and 1926

## RUSSIAN FOREST-SPRING ENCEPHALITIS

This form of encephalitis occurs in Russian forest workers during the late spring and early summer months It is due to a specific virus distinct from the St Louis type but antigenically related to the Japanese B virus Virus reservoirs have been found in rodents and the disease is quite likely transmitted by ticks

## WEST NILE ENCEPHALITIS

This disease has been reported from Africa It is due to a specific virus closely related immunologically to the other types

## TREATMENT OF THE VIRUS ENCEPHALIDES

At present there is no specific treatment and symptomatic therapy is indicated Headache and the meningeal signs may be alleviated by lumbar puncture and by hypertonic solutions The sulfa preparations and the presently available antibiotics are of no value Convalescent serum has not proved to be of value While vaccines have been produced for some types their worth has not been established

## SECONDARY ENCEPHALITIS

Encephalitis may occur in the course of almost any acute infectious disease but particularly following the exanthemata such as measles chickenpox mumps scarlatina and pertussis It may follow rabies or smallpox vaccination Clinically such encephalides are characterized by fever clouding of consciousness and other mental symptoms drowsiness, convulsions paralysis and other neurologic signs Treatment is symptomatic and there are frequently sequels such as mental retardation behavior disorders convulsions and residual neurologic defects

Toxic substances such as lead carbon monoxide and arsenic may produce an encephalophathy with symptoms and sequels similar to those found in the secondary encephalitis

## EPILEPSY

Epilepsy is a loss of consciousness which may be momentary called *petit mal*, or which may be prolonged for minutes or more and be accompanied by a convulsion (*grand mal*) Furthermore certain mental states such as amnesia automatism or periods of excitement may take the place of the fit (Psychomotor seizure) There are two main groups of epilepsy The symptomatic in which epilepsy is a symptom of some underlying neurologic disorder such as brain tumor or paresis and idiopathic or essential epilepsy in which no cause for the seizures can be detected In the so called idiopathic type of the disease very little indeed has been found in the brain to account for the attacks Involvement of the ammon s horn occurs frequently but is probably a result of the disease and not the cause of it Occasionally one finds thickening of the pia and an excessive collection of fluid over the cortex The ventricles may be dilated and drawn to one side Occasionally evidence of an attack of encephalitis may be found but this is not common The cerebrospinal fluid shows no constant alteration and the pressure is normal or low

*Etiology* —Most cases of idiopathic epilepsy develop before the age of twenty five years and a large percentage appear before the age of six years or before puberty Convulsions occurring after twenty five or thirty years of age should always cause a vigorous search to be made for evidence of gross intracranial disease Evidence of old injury to the brain various toxemias, and

alcohol should be considered as the possible cause Epilepsy may occur late in life on an arteriosclerotic basis and is referred to as *epilepsia tarda* The most important etiologic factor is heredity which in some series, may be as high as 50 per cent Heredity may not be direct, but may be passed on as an evidence of *instability* *The incidence* of epilepsy due to congenital syphilis is probably not more than 1 per cent Convulsions of course may occur in individuals who have congenital syphilis either of the paretic or meningo encephalitic type Alcoholism in the parents particularly if the child is conceived during a debauch is supposed to account for a number of epileptics Difficult or prolonged labor especially with instrumentation is probably an important etiologic factor in the production of convulsions At least 10, and perhaps as high as 20 per cent of normal babies have blood in the spinal fluid after birth and this may later serve as a predisposing factor in the production of convulsions In certain cases of prolonged labor with asphyxiation changes may occur in the cortical cells which may later on be a cause of epilepsy The influence of a severe fright in the production of convulsions is probably not great but we have seen a few cases in which the history at least indicated that the first fit occurred after a severe fright Emotional turmoil may be a precipitating factor Convulsions frequently occur in susceptible children in the early stage of infectious diseases especially scarlet fever and an infectious disease may produce changes in the brain which later on predispose the individual to convulsions An occasional case of epidemic encephalitis develops epilepsy as a sequel Convulsions may ensue as the result of allergic reaction to food and other articles but in our experience allergy is rare as a cause

The importance of the so-called reflex epilepsy has been greatly overestimated A few patients suffering from intestinal parasites undoubtedly have convulsions which are probably *not reflex*, but due to the toxemia produced by the infestation and while the removal of the worms may cause a cessation of the fits, they may not be entirely arrested

Various intoxicants may produce convulsions, the commonest one being alcohol There are quite a few people who have fits when they indulge excessively in alcohol and as long as they refrain from use of this drug they do not have convulsions Repeated attacks of delirium tremens may produce changes in the meninges and cortex of sufficient degree to cause recurring spasms In France, where absinthe drinking was common, the so-called absinthe epilepsy was seen Epileptics are not usually alcoholic, but if an epileptic does take alcohol either moderately or to excess he will have a greater number of convulsions than if he refrained from the use of the drug

The occurrence of seizures during pregnancy while often attributed to a toxemia as the result of that state, is quite often due to epilepsy Epileptiform seizures may occur after severe head injury The percentage of cases however which develop a convulsive state is not great probably about 7 per cent It has been proved experimentally that in animals which have been subjected to head trauma convulsants such as absinthe or camphor will more readily cause fits This is an important point from a medico legal standpoint as well as from other considerations Scarring of the brain, with distortion of the ventricular system especially with the pulling of the ventricle toward the side of the lesion occurs In the histories of *epileptics it is* common to see scarlet fever diphtheria or other infections given as the cause of the first convulsion Gross organic disease of the brain such as tumor syphilis abscess and vascular disease sometimes cause fits especially if the person is predisposed by heredity Generalized convulsions however are not common in gross organic disease of the brain except paresis

Chronic poisonings (as lead) heart block (Stokes Adams syndrome) uremia and tetany may all produce convulsions as will also hyperinsulinism The occurrence of spasms during infancy from any cause whatsoever is frequently the forerunner of epilepsy later in life

While it is readily seen therefore that there are numerous factors which must be considered in arriving at a diagnosis in a

patient who has convulsions it is quite true that there are many patients in whom no cause for the fits can be found

While Jacksonian fits are frequently due to organic disease of the brain such as a tumor or syphilis they also occur in idiopathic epilepsy Jacksonian fits do not in themselves indicate an operable lesion The history shows that the fit often begins on one side and may even be localized there for sometime before spreading to the other

*Symptoms* — The vast majority of epileptic seizures come under the heading of *petit mal or grand mal* The attack of petit mal or minor epilepsy is characterized by a sudden loss of consciousness which occurs without warning without a convulsion and without the patient falling to the ground the whole affair lasting but a few seconds The minor attacks may come on at any time and often *escape notice of the family As a rule the* patient suddenly stops what he is doing stares straight ahead the face becomes pale and there may be a slight movement of the tongue and lips or eyes and more rarely of an extremity the patient may yawn make chewing or swallowing movements and then frequently rubs his face and the fit is over The patient often refers to these attacks as bilious or dizzy spells The epileptic may have an enormous number of attacks of petit mal in one month Petit mal attacks may occur without major fits but as a rule are associated with them The patient suffering from major attacks may have them disappear under treatment only to be replaced by minor spells

*Pyknolepsy* is a type of minor epilepsy characterized by the great number of attacks It usually occurs in children and in many cases the attacks often abruptly disappear never to return but in some cases grand mal attacks eventually ensue The ordinary anti-epileptic remedies have little if any effect on attacks of pyknolepsy

Whether or not *narcolepsy* is a variety of epilepsy is a disputed point It is a condition in which an irresistible tendency to sleep occurs the sleep apparently being natural It is likely to occur during any monotous activity but it may occur while the patient is walking along the street riding in a conveyance or playing games The narcoleptic frequently under emotion, especially laughter, has extreme weakness of the legs which give way and he sinks to the ground powerless, but usually conscious (cataplexy) Narcolepsy may follow epidemic encephalitis Ephedrine Benzedrine or Dexedrine by mouth in moderate doses daily has given some favorable results in the treatment of narcolepsy

The grand or major attack in epilepsy is the most dramatic part of the disease and is often preceded by a change in disposition of the patient or by vertigo As a rule however it begins suddenly with unconsciousness In about one-half the cases it is preceded by a warning or *aura* which is a subjective sensation referable to various parts of the body or special senses One of the commonest of aurae is that referable to the epigastrium The patient says he has a *peculiar feeling in the pit of the stomach* which ascends to the head and when it reaches the eyes he becomes unconscious He may have a visual aura which may resemble the scintillating scotomata of migraine He may see animals bright lights or something which appears in the distance which rushes toward him producing unconsciousness when it strikes him Sometimes the aura is referable to an extremity or one side of the body and consists of a paresthesia or dysesthesia The aura may consist of tinnitus which seems to begin in the distance and rapidly approaches the person The next step in the fit is a *cry* or guttural noise which occurs in about half of the cases The cry is often loud and piercing and rather terrifying to the listener If standing the epileptic *falls* and frequently injures himself Many epileptics pitch suddenly forward or backward and as a result this type of case has many injuries and scars on the face In the tonic phase of the *fit* the entire body becomes rigid in extension If the tongue or cheek is caught between the jaws as they are closed it may be severely bitten The patient may assume an attitude of opisthotonos and occasionally one of decerebrate rigidity The pupils will contract then dilate and become fixed to light the muscles of respiration being fixed in the tonic phase respiration is impossible and the patient becomes cyanotic The *tonic*

alcohol should be considered as the possible cause Epilepsy may occur late in life on an arteriosclerotic basis, and is referred to as *epilepsia tarda* The most important etiologic factor is heredity which, in some series may be as high as 50 per cent Heredity may not be direct but may be passed on as an evidence of instability The incidence of epilepsy due to congenital syphilis is probably not more than 1 per cent Convulsions of course, may occur in individuals who have congenital syphilis either of the paretic or meningo encephalitic type Alcoholism in the parents, particularly if the child is conceived during a debauch is supposed to account for a number of epileptics Difficult or prolonged labor especially with instrumentation is probably an important etiologic factor in the production of convulsions At least 10 and perhaps as high as 20 per cent of normal babies have blood in the spinal fluid after birth and this may later serve as a predisposing factor in the production of convulsions In certain cases of prolonged labor with asphyxiation changes may occur in the cortical cells which may later on be a cause of epilepsy The influence of a severe fright in the production of convulsions is probably not great but we have seen a few cases in which the history at least indicated that the first fit occurred after a severe fright Emotional turmoil may be a precipitating factor Convulsions frequently occur in susceptible children in the early stage of infectious diseases especially scarlet fever and an infectious disease may produce changes in the brain which later on predispose the individual to convulsions An occasional case of epidemic encephalitis develops epilepsy as a sequel Convulsions may ensue as the result of allergic reaction to food and other articles but in our experience allergy is rare as a cause

The importance of the so called reflex epilepsy has been greatly overestimated A few patients suffering from intestinal parasites undoubtedly have convulsions which are probably not reflex but due to the toxemia produced by the infestation and while the removal of the worms may cause a cessation of the fits they may not be entirely arrested

Various intoxicants may produce convulsions the commonest one being alcohol There are quite a few people who have fits when they indulge excessively in alcohol and as long as they refrain from use of this drug they do not have convulsions Repeated attacks of delirium tremens may produce changes in the meninges and cortex of sufficient degree to cause recurring spasms In France, where absinthe drinking was common the so-called absinthe epilepsy was seen Epileptics are not usually alcoholic, but if an epileptic does take alcohol either moderately or to excess he will have a greater number of convulsions than if he refrained from the use of the drug

The occurrence of seizures during pregnancy while often attributed to a toxemia as the result of that state is quite often due to epilepsy Epileptiform seizures may occur after severe head injury The percentage of cases, however, which develop a convulsive state is not great probably about 7 per cent It has been proved experimentally that in animals which have been subjected to head trauma convulsants such as absinthe or camphor will more readily cause fits This is an important point from a medico legal standpoint as well as from other considerations Scarring of the brain with distortion of the ventricular system especially with the pulling of the ventricle toward the side of the lesion occurs In the histories of epileptics it is common to see scarlet fever diphtheria or other infections given as the cause of the first convulsion Gross organic disease of the brain such as tumor syphilis abscess and vascular disease sometimes cause fits especially if the person is predisposed by heredity Generalized convulsions however are not common in gross organic disease of the brain except paresis

Chronic poisonings (as lead) heart block (Stokes Adams syndrome) uremia and tetany may all produce convulsions as will also hyperinsulinism The occurrence of spasms during infancy from any cause whatsoever is frequently the forerunner of epilepsy later in life

While it is readily seen therefore that there are numerous factors which must be considered in arriving at a diagnosis in a

of a religious nature. For the maniacal phase after a fit the patient is usually amnesic. This condition may last from a few hours to weeks. Occasionally an automatic state may be a substitute for a fit. About 10 per cent of epileptics after a fit are quarrelsome, destructive, may commit criminal acts, and often wander away.

Epilepsy is occasionally used as a defense for crime but all epileptics who commit crimes are not irresponsible. It might truthfully be said, however, from a medical standpoint that in most instances an epileptic has reduced responsibility.

*Status epilepticus* is one of the most severe manifestations of epilepsy and a frequent cause of death. In status, which consists of a series of convulsions without consciousness being regained between attacks, the patient may have from two to hundreds of seizures. There are some epileptics who apparently have their fits only in series and who may then go some time without having any major attacks. After status, stupor becomes deep, the temperature rises to 103° to 106° F. or higher, the breathing becomes noisy and occasionally Cheyne-Stokes, the heart action may become irregular, and edema of the lungs ensues and frequently causes death. Trophic sores are common in some epileptics who have status. Occasionally status epilepticus is limited to one side of the body, when the term *status hemiepilepticus* is applied. Occasionally after a convulsion or particularly after a series of convulsions an exhaustion paralysis of one side may occur; this paralysis usually clears up in a few hours to days.

In *epilepsia partialis continua* the attacks are limited, as a rule, to an extremity or a part of an extremity, or to the face and tongue. This condition is usually due to gross organic disease of the brain, such as syphilis, tumor or encephalitis, but may occur in idiopathic epilepsy. The attacks of epilepsy may be diurnal, nocturnal or both.

The frequency of the fits varies greatly from one every few months to numerous fits daily. The fortunate epileptic is he who has only an occasional major attack and that at night. The individual who has petit mal spells is likely to have numerous ones. As he grows older, the frequency of his fits, however, may be reduced.

Atypical fits or epileptic variants occur. Among them abdominal epilepsy, characterized by paroxysms of acute abdominal pain and electroencephalographic abnormalities, have been described (Moore).

*Diagnosis.*—In arriving at the diagnosis of epilepsy, which can be satisfactorily done in the vast majority of cases by the history, it is sometimes necessary to observe a convulsion, especially if the question of hysteria enters into the picture. Hysterical convulsions, which are most uncommon in this country, are the opposite of the epileptic ones. They occur during the daytime; the typical aura and cry are absent; the patient practically never injures himself; the tongue is not bitten; the sphincters do not relax, and the tonic and clonic phases of the ordinary epilepsy are lacking. The pupils react to light, the conjunctival reflex is preserved and the Babinski sign is never seen. The patient does not sleep after an hysterical fit, does not vomit and, the atmosphere being cleared by an attack, usually feels better. Strong suggestion may stop the attack, which also will cease if the patient is left alone. While the term hystero-epilepsy is not accepted, some epileptics have hysterical fits as well. The later in life the first attack of epilepsy begins, the more thorough should be the search for conditions capable of producing convulsions, especially a cerebral neoplasm, which may exist for years without localizing signs. The confused state with a fear of fainting complained of by many psychoneurotics may also be mistaken for minor epilepsy.

The relation of infantile convulsions to epilepsy is an important one. Although every patient who has infantile convulsions does not become an epileptic, many of them do.

*Electro-encephalography in Epilepsy.*—Electro-encephalography is of value in the diagnosis of some cases of epilepsy, particularly when the clinical description of the seizure may not be clear, when the seizures are infrequent, or when they cannot be clinically differentiated from hysteria. A routine electro-encephalogram is of value in the diagnosis in 58 per cent of patients

*phase* lasts from a few seconds to a minute or two, and is followed by the *clonic stage* which lasts from a few seconds to four or five minutes The head jerks violently, the muscles of the extremities are vigorously contracted and relaxed and are the seat of electric-like movements The contraction of the muscles of mastication causes a frothy saliva to exude from the mouth and, if the tongue lips or cheeks have been bitten the saliva is blood tinged Dislocation of joints especially the shoulder, is not infrequently produced in this phase The facial muscles twitch the eyeballs roll around and respiration is noisy The pupillary reflexes remain lost in this phase and the deep reflexes are obtained with difficulty The pulse is small and rapid and the blood pressure, which may be slightly elevated at first drops during the spasm The Babinski reflex may frequently be obtained after the convulsion Hemorrhages may occur in various parts of the body especially into the brain and conjunctiva An occasional convulsive movement may persist for some minutes after the severity of the fit has subsided The epileptic usually sleeps after an attack the period of sleep may vary from a few minutes to a number of hours Quite often after an attack and either before or after the stupor the patient performs purposeless automatic acts in which he attempts to undress or fumbles with his clothes When the patient recovers consciousness he practically always complains of headache which may last for hours Vomiting is an occasional symptom after a fit As a rule there is complete amnesia for the spell and this period may last a number of days during which the patient may wander away and perform automatic deeds (fugue) Owing to the severity of the muscular contractures the epileptic usually has muscular soreness after a fit The temperature is slightly elevated and the patient passes considerable urine after a spell and it often contains albumin and casts which are not found on subsequent examinations but which may give rise to confusion in the diagnosis Relaxation of the sphincters especially the urinary sphincter occurs either during the tonic or clonic stage It does not occur in all attacks but is a symptom at some time in the history of most epileptics

In an attack of the so called rare *epilepsia procursiva* the patient suddenly begins to run usually forward and at the end of a few seconds running he may become confused or may fall and have a fit

Many gradations of epileptic fits occur between the attack of petit mal and the grand seizure Some become unconscious and pitch forward and that is the entire attack others fall and have a few convulsive movements and the attack is over Some have what they themselves call the "jerks," in which violent muscle spasms occur, often of sufficient severity to throw the patient to the ground and as a rule without unconsciousness These muscle spasms are accompanied by considerable pain

The disposition of an epileptic is sometimes trying He may be noncooperative quarrelsome and pugnacious given to attacks of depression suspicious hypersensitive and may have a violent temper He is frequently loquacious and will talk unceasingly often in a monotonous tone of his complaints Some are pathologic liars and egotistic Their memory is sometimes poor and they tend to become asocial However there are many epileptics who show no outstanding defects in personality and behavior and if their fits are controlled they are able to make a satisfactory adjustment to society Mental deterioration sometimes ensues and in the end mental dilapidation may be complete Mental disturbances may occur before or after a seizure or the so called *psychic equivalent* may be the manifestation of a fit In the psychomotor attacks the patient may exhibit abnormal and psychotic behavior for which there is usually an amnesia on recovery Fortunately the psychic equivalent is not common but in it the patient may develop a homocidal mania in which he may kill one or a number of people Murders committed in this phase are often extremely brutal The presently available evidence suggests that the psychomotor disturbances arise from a focus in the anterior temporal lobe After any variety of attack the patient may be violent confused or delirious He also frequently suffers from delusions and hallucinations especially the latter and the symptoms frequently are

of a religious nature For the maniacal phase after a fit the patient is usually amnesic This condition may last from a few hours to weeks Occasionally an automatic state may be a substitute for a fit About 10 per cent of epileptics after a fit are quarrelsome destructive, may commit criminal acts and often wander away

*phase* lasts from a few seconds to a minute or two, and is followed by the *clonic stage* which lasts from a few seconds to four or five minutes The head jerks violently, the muscles of the extremities are vigorously contracted and relaxed, and are the seat of electric like movements The contraction of the muscles of mastication causes a frothy saliva to exude from the mouth and if the tongue lips or cheeks have been bitten the saliva is blood tinged Dislocation of joints especially the shoulder, is not infrequently produced in this phase The facial muscles twitch the eyeballs roll around and respiration is noisy The pupillary reflexes remain lost in this phase and the deep reflexes are obtained with difficulty The pulse is small and rapid and the blood pressure, which may be slightly elevated at first drops during the spasm The Babinski reflex may frequently be obtained after the convulsion Hemorrhages may occur in various parts of the body especially into the brain and conjunctiva An occasional convulsive movement may persist for some minutes after the severity of the fit has subsided The epileptic usually sleeps after an attack the period of sleep may vary from a few minutes to a number of hours Quite often after an attack and either before or after the stupor the patient performs purposeless automatic acts in which he attempts to undress or fumbles with his clothes When the patient recovers consciousness he practically always complains of headache which may last for hours Vomiting is an occasional symptom after a fit As a rule there is complete amnesia for the spell and this period may last a number of days during which the patient may wander away and perform automatic deeds (fugue) Owing to the severity of the muscular contractures the epileptic usually has muscular soreness after a fit The temperature is slightly elevated and the patient passes considerable urine after a spell and it often contains albumin and casts which are not found on subsequent examinations but which may give rise to confusion in the diagnosis Relaxation of the sphincters especially the urinary sphincter occurs either during the tonic or clonic stage It does not occur in all attacks but is a symptom at some time in the history of most epileptics

In an attack of the so called rare *epilepsia procursiva* the patient suddenly begins to run, usually forward and at the end of a few seconds running he may become confused or may fall and have a fit

Many gradations of epileptic fits occur between the attack of petit mal and the grand seizure Some become unconscious and pitch forward and that is the entire attack others fall and have a few convulsive movements and the attack is over Some have what they themselves call the jerks, *in which violent muscle spasms occur, often* of sufficient severity to throw the patient to the ground and as a rule without unconsciousness These muscle spasms are accompanied by considerable pain

The disposition of an epileptic is sometimes trying He may be noncooperative quarrelsome and pugnacious given to attacks of depression suspicious hypersensitive and may have a violent temper He is frequently loquacious and will talk unceasingly often in a monotonous tone of his complaints Some are pathologic liars and egotistic Their memory is sometimes poor and they tend to become asocial However there are many epileptics who show no outstanding defects in personality and behavior and if their fits are controlled they are able to make a satisfactory adjustment to society Mental deterioration sometimes ensues and in the end mental dilapidation may be complete Mental disturbances may occur before or after a seizure or the so-called *psychic equivalent* may be the manifestation of a fit In the psychomotor attacks the patient may exhibit abnormal and psychotic behavior for which there is usually an amnesia on recovery Fortunately the psychic equivalent is not common but in it the patient may develop a homocidal mania in which he may kill one or a number of people Murders committed in this phase are often extremely brutal The presently available evidence suggests that the psychomotor disturbances arise from a focus in the anterior temporal lobe After any variety of attack the patient may be violent confused or delirious He also frequently suffers from delusions and hallucinations especially the latter and the symptoms frequently are

important adjuncts in the treatment of epilepsy

In the past, many different varieties of diets have been recommended for the epileptic Today the epileptic is permitted almost any well balanced diet his palate craves A ketogenic diet and dehydration have been advocated by some The ketogenic diet starvation and dehydration are more likely to cause beneficial results in children in whom remissions are common without any method of treatment The good obtained from these methods of treatment in adults is meager

Many drugs have been recommended for the treatment of epilepsy Until recently the drug most in vogue was phenobarbital (luminal) The dose will vary with the age and weight of the patient but for the ordinary young adult 1½ to 6 grains (0 1 to 0 4 gm ) may be prescribed daily If more than 1 grain is given daily it should be in divided doses, with the largest dose at bedtime If given to excess it will produce mental dullness slurred speech pronounced lethargy and occasionally a rash which simulates scarlet fever Myerson and others have advocated giving benzedrine sulphate (amphetamine) to their patients who require large doses of luminal in order to conteract the lethargy and dullness If luminal is used in the treatment of epilepsy it should not be suddenly withdrawn because status epilepticus may ensue If only one dose of luminal is given a day it is more convenient for the patient to take it at bedtime Dilantin (sodium diphenyl hydantoinate) was introduced by Merritt and Putnam in 1938 as a drug which had a high anticonvulsant action with little or no hypnotic or sedative effect This drug has proved to be of value in many cases in which the seizures were not adequately checked by phenobarbital It appears to be of more value in cases with grand mal and psychomotor equivalents than in petit mal The dose varies from 1½ grains to 6 grains (0 1 gm to 0 4 gm ) a day depending on the frequency and severity of the seizures In patients previously taking phenobarbital the transition to dilantin should be gradual otherwise the frequency of attacks may temporarily be increased Toxic symptoms such as ataxia, dizziness, mild nausea tremor, blurred vision diplopia dermatitis and hyperplasia of the gums may occur We prefer to limit the use of this drug to those cases not satisfactorily controlled by phenobarbital Until the advent of luminal the remedy most prescribed was bromide five to 30 grains (0 3 to 2 gm ) or more may be prescribed three or four times daily Prolonged administration may give rise to toxic symptoms, the chief of which are dermatitis mental lethargy and psychotic manifestations Mensantoin (3 methyl-5 phenyl 5 ethylhydantoin) is helpful in some cases with grand mal seizures cases that cannot be controlled by dilantin It has some undesirable toxic effects the most serious of which is the production of pancytopenia Frequent checks on the blood count are therefore necessary In the treatment of petit mal the drug of greatest value is tridione This drug likewise may give rise to aplastic anemia and agranulocytic angina In some patients it produces an annoying glare phenomenon which while not harmful to vision is still troublesome

The choice of drugs and the dosage must be individualized With a little trial and error experimentation the optimum combination and dosage can be obtained

Operations on the brains of epileptics produce rarely good results A patient who has had epileptic fits for many years beginning on one side of the body or in one extremity and without definite localizing signs between attacks or any other evidence to indicate an intracranial mass lesion should not be operated upon Excision of part of the motor cortex has been tried unsuccessfully In the posttraumatic type of epilepsy with scarring of the brain the excision of the scar has been advised and improvement reported

The treatment of an attack of status is a difficult one Epsom salts should be administered if necessary by a nasal tube and 3 ounces given in 6 ounces of water by rectum The use of sodium luminal intravenously in doses of 5 to 10 grains (0 3 to 0 6 gm ) should be employed and if the attacks still persist a lumbar puncture may be performed Chloral and bromides by

with seizures, while in 42 per cent it is of little or no value

The electrical pattern obtained during an actual seizure is distinctive for each of the three main clinical types of seizures

In the interval between clinical attacks, the electro-encephalogram may record abnormal wave patterns which tend to correspond with the type of clinical seizure manifest in the particular case

*Prognosis* —The prognosis in epilepsy is poor as regards cure but the outlook for life is good

The percentage cured of attacks is small and probably falls between 5 and 10 If the first seizure occurs late in life the outlook is better than if it had happened early A patient with one or two fits a year will naturally respond more favorably than one who has daily attacks Bad heredity also affects the prognosis as does also the history of status epilepticus

*Treatment* —While the treatment of epilepsy offers poor results as far as cure is concerned sufficient and prompt treatment does reduce the number and severity of the fits in a large percentage While it is true that even the most painstaking search for an etiologic factor may produce nothing of importance many conditions may be found which can be remedied and the patient given improved general health as a result

The *prophylaxis* of epilepsy should begin before conception The question of marriage should be individualized Prevention of injuries at birth and their proper treatment if present are important The nervous high-strung child especially he who has had infantile convulsions or such diseases which may be closely allied to epilepsy such as night terrors, sleep walking nocturnal enuresis or the child who has had severe head injury with unconsciousness should be closely observed by the medical attendant and kept in good general health The history of infantile convulsions should call for close observation of the development of the child, who should be treated as a potential epileptic If a child has a convulsion which has no relation to an acute infectious disease, head trauma or other obvious cause treatment should be instituted immediately to cut down the tendency to develop recurring attacks of unconsciousness with convulsions It must be borne in mind that there are many epileptics who having had a few convulsions before the age of six years may have no further attacks until puberty or later

Nothing can be done to cut short an attack once it has begun, although certain patients feel that sometimes they may abort an attack by various maneuvers such as tightly squeezing the extremity in which the aura appears In the attack itself the chief concern should be to prevent injury Some object should be inserted between the teeth to prevent biting of the tongue lips and cheek, such as a spoon or tongue depressor padded with cotton and a bandage A pillow should be placed under the head or the head supported to prevent its being knocked against the floor Sometimes an extremity must be supported because in the severe clonic stage it may be injured by hitting the floor or surrounding objects After the convulsion is over the patient should be watched and prevented from doing automatic acts which are dangerous to himself or others and to see that he does not wander away The epileptic should be allowed to sleep out the fit and no effort should be made to hasten his recovery from the postepileptic stupor

The subject of the epileptics employment is an important one Although in the past it was practically impossible for a known epileptic to keep a job today many are gainfully employed The epileptic should never be allowed to continue work which is obviously hazardous such as working around machinery driving an automobile any job which takes him off the ground railway work in fact anything which might prove to be injurious to himself and others if he had an attack Swimming should not be permitted Work is an excellent thing but excessive fatigue should be avoided Life in the country either on a farm or in a colony for the treatment of epileptics is the best environment for some of these unfortunate people Stimulants which in themselves can cause convulsions should be prohibited Alcohol and tobacco would fall in this group Rigid care of the gastro-intestinal tract and exercise are extremely

be regarded as an aura While the hemianopsia practically always clears up occasionally it becomes permanent Temporary paralysis of an ocular nerve especially the third sometimes occurs and after lasting a few weeks or rarely longer passes away Hemiplegia or hemiparesis paresthesia or dysesthesia limited to one side of the body and aphasia may complicate an attack of migraine Psychotic episodes resembling very much those seen after an epileptic fit such as confusion, maniacal outbreaks and an hallucinatory state are rare happenings but give an added similarity to certain manifestations of epilepsy and migraine *The frequency of the attacks vary from one* or two a month to about the same number a year They may disappear at the menopause

The *diagnosis* of migraine is usually simple especially when the visual phenomena accompany it A case of migraine complicated with a paralytic phenomenon may be mistaken for a tumor or a vascular accident After a patient has had migraine for many years is advanced in years and arteriosclerotic it may be difficult to differentiate between a paralytic state due to hemicrania and vascular disease Sinus disease, syphilis trigeminal neuralgia especially the atypical forms and headache due to eye strain have occasionally to be differentiated Headaches *of psychogenic origin may be confused with* migraine The course of migraine is not easily altered While the patient is free *from pain between headaches they are likely* to recur until the time of the menopause and in many patients persist throughout life Histamine headaches are also usually unilateral and are accompanied by symptoms of vasodilatation on the same side such as edema of the eyelids lacrimation and running of the nose The onset usually is after the age of 50 and the headaches usually come on during sleep

*Treatment* —In the management of a case *of migraine as in epilepsy the initial* step should be to place the patient in the best possible condition of general health and diseased states in any part of the body should be corrected The avoidance of both mental and physical fatigue a definite number of hours sleep nightly and regu*larity in the habits of life are essential* Lennox states that ergotamine tartrate will bring relief in nine tenths of patients and believes *the action is specific for headaches* of migraine type The dose is a 1 cc ampule containing 0 5 mg given intramuscularly and 2 tablets *each containing 1 mg* by mouth hourly until the headache is relieved or 6 tablets taken

*Dihydroergotamine* (DHE 45) *is less toxic* and probably as effective Caffergone can be administered orally but it is questionable *if it is as effective The use of luminal* may be advised between headaches, and it frequently reduces the number and severity of *the attacks If any evidence of allergy can* be found a lead for treatment may be obtained in that way Massive doses of thiamin chloride have been advocated as being beneficial but in our experience the results have been very poor Endocrine therapy has been tried usually with no benefit Abnormal conditions in the gastrointestinal tract should be corrected and the diet should consist of simple easily digestible foods If there is evidence of histamine sensitivity desensitization may be tried

*Headache* may be due to many causes such as sinusitis ocular disease anemia hypertension emotional disturbances various toxemias, brain tumors and other conditions of the nervous system These *conditions are discussed elsewhere*

# THE PERIPHERAL NERVOUS SYSTEM

## NEURITIS

*Definition* —Neuritis may be defined as an infection of a peripheral or cranial nerve However when the etiologic agent is non infectious the term neuropathy is more proper

*Etiology* —The causes of neuritis are trauma pressure as from crutches tight bandages or casts and pressure from tumors intoxication by alcohol lead and arsenic and infectious diseases Chronic focal infection often is an added etiologic factor in cases of multiple neuritis due for *example to alcohol Beriberi* is due to a

rectum have been recommended in the treatment of status but the depressing effect of chloral is great and it should be watched for. It is interesting to observe that in many cases of severe status an extreme degree of dehydration ensues yet the convulsions continue. The patient in status must be carefully watched *for signs of pulmonary edema* and heart failure, and if either one of these complications occurs appropriate treatment should be instituted. It is occasionally necessary to give a general anesthetic to stop status epilepticus. During an attack of status trophic sores on the heels and buttocks not infrequently occur and to prevent this the patient's bed should be changed frequently and padded and the back bathed with alcohol and powdered often. There are many epileptics who have a confusional or delusional episode not only after an attack of status but even after a single fit and it is necessary to confine such a patient *rather closely* to a room in which the windows are protected, dangerous objects removed and the door locked.

The psychotherapeutic treatment of an epileptic has an important place. He *should be encouraged and a continued effort* made to get him to cooperate in his treatment. In some cases the best results are obtained by placing the patient in an institution where he develops a routine and a method of living that is best suited to his disease.

## MIGRAINE

*Synonyms.*—Sick headache. Hemicrania.

Migraine is a periodic headache limited to one side of the head, and accompanied by certain eye symptoms and vomiting. The attack often terminates in sleep.

The most important factor in the *etiology* of migraine is heredity. There is a relationship between migraine and epilepsy; some believe that a person suffering from migraine is more likely to produce epileptic children than an epileptic. This is questionable. Attacks of migraine may cease and be replaced by epilepsy, *or* attacks of the two diseases may alternate. Evidence exists that migraine may be an allergic manifestation. Certain foods have been known to precipitate an attack of migraine in which eosinophilia may also occur. Histamine sensitivity has been *thought to be the cause* of periodic headache of both the migraine and non-migraine type. Indiscretions in diet, worry and exhaustion may serve to initiate an attack. Various endocrine abnormalities have been cited as the *etiologic factor in migraine* but the case has not been proved. Other facts, such as the relation of migraine to menstruation, with its occasional disappearance during pregnancy or lactation or at the menopause have been used to support the theory that the ductless glands are at fault. A theory as to the causation of the attacks is that vascular spasms occur probably secondary to sympathetic instability. Attacks of hemiplegia, of aphasia and of hemianopsia during the attack of migraine lend strength to this theory. Some consider migraine a sensory form of epilepsy. The condition is about twice as common in females as in males.

*Symptoms.*—The attack of migraine is usually ushered in by a general ill feeling, drowsiness, slight pain in the head and dizziness. The appetite may be voracious for a day or so prior to the onset of the attack. *These symptoms may last for a* number of hours and are followed by a severe headache which is limited to one side of the head in the attack although it may be frontal or occipital in location. Some patients have the pain on the same side in *all attacks and in others the locality may* vary. It is an unbearable excruciating type of headache and frequently gives the patient thoughts of suicide. Sometimes the head is tender to touch. The headache lasts from a few hours to two or three days and is practically always accompanied by vomiting. After the acute headache subsides a dull ache may be present for a few hours. There is a distinct periodicity to the attacks *which have a tendency to occur at the* menstrual periods in women. The headache is aggravated by noise, light and confusion and the patient suffering from a migrainous headache prefers to be alone. Visual disturbances are frequent. Hemianopsia may occur and be accompanied by dazzling lights, bright dots or zig-zagging phenomena in the blind fields. In some patients the hemianopsia precedes the headache and can

be regarded as an aura. While the hemianopsia practically always clears up, occasionally it becomes permanent. Temporary paralysis of an ocular nerve, especially the third, sometimes occurs and after lasting a few weeks or rarely longer passes away. Hemiplegia or hemiparesis, paresthesia or dysesthesia limited to one side of the body and aphasia may complicate an attack of migraine. Psychotic episodes resembling very much those seen after an epileptic fit, such as confusion, maniacal outbreaks and an hallucinatory state are rare happenings but give an added similarity to certain manifestations of epilepsy and migraine. The frequency of the attacks vary from one or two a month to about the same number a year. They may disappear at the menopause.

The *diagnosis* of migraine is usually simple *especially when the visual phenomena accompany it*. A case of migraine complicated with a paralytic phenomenon may be mistaken for a tumor or a vascular accident. After a patient has had migraine for many years, is advanced in years and arteriosclerotic, it may be difficult to differentiate between a paralytic state due to hemicrania and vascular disease. Sinus disease, syphilis, trigeminal neuralgia, especially the atypical forms, and headache due to eye strain have occasionally to be differentiated. Headaches of psychogenic origin may be confused with migraine. The course of migraine is not easily altered. While the patient is free from pain between headaches they *are likely* to recur until the time of the menopause and in many patients persist throughout life. Histamine headaches are also usually unilateral and are accompanied by symptoms of vasodilatation on the same side, such as edema of the eyelids, lacrimation and running of the nose. The onset usually is after the age of 50 and the headaches usually come on during sleep.

*Treatment.*—In the management of a case of migraine, as in epilepsy, the initial step should be to place the patient in the best possible condition of general health and diseased states in any part of the body *should be corrected*. The avoidance of both mental and physical fatigue, a definite number of hours sleep nightly and regularity in the habits of life are essential. Lennox states that ergotamine tartrate will bring relief in nine-tenths of patients, and believes the action is specific for headaches of migraine type. The dose is a 1 cc ampule containing 0.5 mg given intramuscularly and 2 tablets each containing 1 mg by mouth hourly until the headache is relieved or 8 tablets taken.

Dihydroergotamine (DHE 45) is less toxic and probably as effective. Caffergone can be administered orally but it is questionable if it is as effective. The use of *luminal* may be advised between headaches and it frequently reduces the number and severity of the attacks. If any evidence of allergy can be found, a lead for treatment may be obtained in that way. Massive doses of thiamin chloride have been advocated as being beneficial but in our experience the *results have been very poor*. Endocrine therapy has been tried, usually with no benefit. Abnormal conditions in the gastrointestinal tract should be corrected and the diet should consist of simple, easily digestible foods. If there is evidence of histamine sensitivity, desensitization may be tried.

*Headache* may be due to many causes such as sinusitis, ocular disease, anemia, hypertension, emotional disturbances, various toxemias, brain tumors and other conditions of the nervous system. These conditions are discussed elsewhere.

# THE PERIPHERAL NERVOUS SYSTEM

## NEURITIS

*Definition.*—Neuritis may be defined as an infection of a peripheral or cranial nerve. However, when the etiologic agent is non-infectious, the term neuropathy is more proper.

*Etiology.*—The causes of neuritis are trauma, pressure as from crutches, tight bandages or casts and pressure from tumors, intoxication by alcohol, lead and arsenic and infectious diseases. Chronic focal infection often is an added etiologic factor in cases of multiple neuritis due for example to alcohol. Beriberi is due to a

deficiency of vitamin $B_1$ in the diet In alcoholic multiple neuritis, in addition to the intoxication by alcohol and focal infection, deficiency of vitamin $B_1$ plays a major role

*Pathology*.—If a peripheral nerve is diseased or injured, the nerve beyond the point of involvement undergoes pathologic changes, sometimes the nerve proximal to the site of injury degenerates, even as high as the anterior horns The myelin sheath breaks up into lecithin bodies and fat droplets The cells of the sheath of Schwann proliferate and the axis cylinder splits and becomes fragmented These processes ultimately result in scarring and the formation of connective tissue

*Symptoms*.—These vary depending upon the nerve involved Most nerves are mixed, containing both motor and sensory fibers, so that in practically every case of neuritis there is a disturbance of both motion and sensation The greatest discomfort which the patient has is due to the involvement of the sensory part of the nerve producing pain and paresthesias which may be characterized by the patient as burning pins and needles, tingling or a sensation of bugs crawling over the skin Sometimes especially if the median or sciatic nerve is involved intense burning pain ensues and to this condition the term causalgia has been given Movement intensifies the pain and tenderness occurs if the nerve is pressed upon

*Objective Signs*.—In such cases there will occur some disturbance of sensation which is found in the peripheral distribution of the nerve involved All forms of sensation are involved, touch probably more than the others Hyperesthesia and hyperalgesia may be seen in certain areas of the nerve If the nerve involved is a mixed nerve disturbances of power will occur in the muscles supplied by the nerve This varies from barely perceptible weakness to complete paralysis As a rule the extensor muscles are more affected by neuritis than the flexors The muscles supplied by the affected nerve become atrophic, flaccid and if a deep reflex is present in the domain of the nerve affected it is lost In addition the affected nerves show the reactions of degeneration or the loss of contractility to faradism Fibrillations may occur in multiple neuritis, but are infrequent and if present usually denote anterior horn changes Trophic and vasomotor disturbances may be seen and are due to implication of the sympathetic and trophic fibers present in the peripheral nerve The skin is often tense, shiny, cold and blue Desquamation, occurrence of trophic sores and of trophic conditions of the nails and an increase or loss of sweat may be seen Contractures of the muscles and joints are frequently seen in cases of neuritis especially multiple neuritis and occur most distinctly in patients who are not properly treated

*Diagnosis*.—The diagnosis of neuritis should be made only after a careful diagnostic survey of the individual Joint disease simulates neuritis by producing pain limitation of motion and wasting of the muscles, and should be considered, especially if the pain is confined to one extremity or part of one extremity Arthritis of the shoulder or hip and bursitis in these regions are frequently labelled neuritis in the early course of the illness The reflex activity is increased in arthritis and sensory loss and reactions of degeneration do not occur Any affection which involves the posterior roots of the spinal cord is frequently called neuritis or neuralgia Such conditions as spinal syphilis, spinal tumors and disease of the vertebræ are misdiagnosed early and late Tumors along the course of the nerve especially pelvic sarcomas are frequently called sciatica Pressure of a cervical rib on the brachial plexus is sometimes considered as a neuritis arising in the nerve itself

## Multiple Neuritis (Polyneuritis)

One of the commonest forms of neuritis is multiple neuritis which is due in the vast majority of instances probably 90 per cent to chronic alcoholism The amount of alcohol necessary to produce neuritis varies with the individual just as the amount of alcohol needed to bring about intoxication depends upon the person Some individuals especially women whose nervous systems are especially susceptible to alcohol may develop signs of multiple neuritis after what might be considered moderate drinking Most individuals who consume fairly large

quantities of alcohol, eat small amounts of food or practically none at all. This leads to a vitamin deficiency, especially $B_1$, and the lack has a distinct effect on not only the peripheral, but also on the central nervous system.

Other frequent causes of multiple neuritis are intoxication due to heavy metals (especially lead and arsenic), diabetes, diphtheria and virus infections.

The earliest *symptom*, as a rule, occurs in the feet and is a paresthesia which may be of any description. One of the commonest and most characteristic symptoms is a burning sensation in the toes and feet so intense that the patient often places his feet in cold water, even on a cake of ice, to control the painful sensation. Another common habit of the patient suffering from alcoholic multiple neuritis is to keep his feet uncovered at night because the warmth produced by blankets increases the burning feeling. The paresthesias gradually ascend the feet and legs and about this time involve the fingers and hands. Tenderness on pressure over the nerves, the pressure of shoes and of the feet on the ground when the patient attempts to walk are unbearable. The tenderness of the feet is best elicited by squeezing the feet; this produces pressure on the nerves as they are passing between the metatarsal bones. Weakness and ultimately paralysis of the muscles come on, usually more marked in the extensors, but finally involving all the muscles. The toe and foot drop and the finger and wrist drop are the earliest paralyses seen, but if the patient continues to use alcohol, if he has a focal infection or if an acute infection should attack him he may lose power in all four extremities.

The deep reflexes in the arcs of the affected nerves become diminished and then lost. The paralysis, which is a flaccid one, is accompanied by atrophy, changes in electrical reactions and trophic disorders. All forms of sensation become impaired in a case of any severity. The loss of sensation occurs first in the distal portions of the extremities and even in severe cases may not be found above the ankles and the wrists. If the patient can still walk when first seen and has paralysis, he will usually show a *steppage gait*, which is due to double foot- and toe-drop. Occasionally in the so-called pseudotabes type of multiple neuritis the gait may be ataxic. Sphincter disturbances do not occur as a rule. Cranial nerve symptoms, with the exception of involvement of the optic nerves, are uncommon in alcoholic multiple neuritis but occur more frequently in polyneuritis due to infections. In alcoholic multiple neuritis any of the forms of mental disease due to alcoholism may be seen. But there is one, namely *Korsakoff's psychosis*, characterized by confusion, disorientation, marked loss of memory and confabulation, which is most commonly noticed. Korsakoff's psychosis may occasionally be due to other toxemias, to infections and also we have seen the syndrome after head injury. It may take some months for the individual to reach the height of the illness. If properly handled most patients will recover but some will do so incompletely.

The most important phase in the *treatment* of a case of alcoholic multiple neuritis is to discontinue the use of the drug. A high caloric diet rich in vitamins, plenty of fresh air and sunshine are extremely important in the management of these cases. Preparations of vitamin B should be given in large doses both by mouth and parenterally. The patient should be immediately placed in the best health possible and all foci of infection removed. A sponge mattress should be used and a cradle should be placed over the lower extremities to keep the weight of the bedclothes off those parts. If actual paralysis exists, splints should be applied and the extremities affected placed in a neutral position. This is extremely important because if foot- and wrist-drop are permitted to exist for some time, changes take place in the muscles and tendons which may result in contracture so that the patient will find after he has recovered from multiple neuritis that he cannot walk because of contractures at the ankles or knees. Drugs are often necessary for the relief of pain and paresthesias, but care should be taken that the patient should not be given an opportunity to develop a new habit. Opium and its derivatives should be used only after everything else has been tried and failed. A combination of bromides and

deficiency of vitamin $B_1$ in the diet In alcoholic multiple neuritis, in addition to the intoxication by alcohol and focal infection, deficiency of vitamin $B_1$ plays a major role

*Pathology* —If a peripheral nerve is diseased or injured the nerve beyond the point of involvement undergoes pathologic changes, sometimes the nerve proximal to the site of injury degenerates even as high as the anterior horns The myelin sheath breaks up into lecithin bodies and fat droplets The cells of the sheath of Schwann proliferate and the axis cylinder splits and becomes fragmented These processes ultimately result in scarring and the formation of connective tissue

### Multiple Neuritis (Polyneuritis)

One of the commonest forms of neuritis is multiple neuritis which is due in the vast majority of instances probably 90 per cent to chronic alcoholism The amount of alcohol necessary to produce neuritis varies with the individual just as the amount of alcohol needed to bring about intoxication depends upon the person Some individuals especially women whose nervous systems are especially susceptible to alcohol may develop signs of multiple neuritis after what might be considered moderate drinking Most individuals who consume fairly large

### Sciatica

Sciatica is more frequently seen in males. It frequently is observed after infectious diseases or may be due to chronic focal infection especially in the prostate. It may follow exposure to cold. It may occur after intragluteal medication. It may come on after a heavy lifting or a marked muscular exertion especially in people not used to such exertion. It may be due to herniation of the intervertebral disks. True sciatica is usually unilateral. If double sciatica exists it is imperative to rule out the conditions such as syphilis and tumor of the spinal cord. It may be an occupational disease due to pressure on the nerve due to prolonged sitting.

*Symptoms.*—The onset is usually gradual but in certain infectious cases and in those due to *stretching of the nerve during* physical exertion the signs may come on abruptly. Pain begins as a rule in the buttock and follows the course of the nerve down the back of the thigh, calf, heel and to the foot. While the pain is usually constant it may be paroxysmal and like most pains is worse at night. Coughing, sneezing, jarring and motion aggravate the pain which is usually sharp but may be dull. The patient tries to prevent pain by keeping *the extremity flexed at the ankle and the hip* and if he is in bed he holds the extremity flexed at the knee and abducted. He is likely to stand on the healthy extremity, the gluteal fold is low on the affected side and a scoliosis is usually seen with the convexity toward the diseased area. Anything which stretches the nerve, such as bending forward to touch the floor with the fingers or testing for Lasegue's sign (which is done in the same manner as Kernig's sign) makes the patient *cry out* with pain. Tender points may exist along the course of the nerve. Paralysis and sensory loss are uncommon but the latter especially may occur in the distribution of the nerve. The knee jerk is not affected; in fact, due to the tenseness of the patient, it may be slightly exaggerated. The Achilles reflex is diminished or lost. Muscular atrophy and changes in electrical reactions do not occur except in very rare cases. Trophic and vasomotor signs may be seen.

Most patients will recover although the condition may be very resistant to treatment and persist for months.

As far as the *differential diagnosis* is concerned, a condition should be called sciatica only as a last resort. Careful investigation of the pelvis, rectum and spine with particular search for evidence of syphilis, spinal cord tumors, protrusion of the intervertebral disks, focal infections, evidence of arthritis, especially of the hip and sacro-iliac joint, elimination of flat feet and of arterial disease should be gone into before the diagnosis of sciatica is made.

The most important element in the *treatment* is rest. A combination of bromide and salicylate will quiet the patient and relieve the pain. In view of the fact that the condition may be prolonged, opium and its derivatives should not be used. Heat, either dry or wet, usually gives the patient considerable relief and diathermy over the nerve is sometimes of considerable value. If the pain is very severe 5 to 10 cc. of a 1 per cent solution of novocaine may be injected epidurally in the sacral canal and followed in a few minutes by the injection of 50 cc. of normal sterile saline. Direct injection into the nerve sheath of normal saline or alcohol and stretching of the nerve have been used but usually with poor results. The less stretching and injection done the happier the patient. In rare cases exposure of the nerve and freeing it of adhesions have benefited the patient.

### Peripheral Facial Paralysis (Bell's Palsy, Prosoplegia)

This is probably the commonest type of peripheral neuritis. It is much more frequently seen in the spring and fall and is usually due to exposure and chilling of the face. A facial palsy may be seen in the course of any infectious disease, in ear infection, in tumors of the parotid, tumors in the cerebellopontile angle, syphilis in the cerebellopontile angle and direct trauma to the nerve. It is occasionally the result of operations on the parotid or on the ear. Tetanus, especially when the wound of entrance is about the face, may produce

salicylates will often serve to quiet the patient and to relieve him of pain. If insomnia is present, as it often will be early in the treatment, such drugs as the barbiturates may be tried. The gastrointestinal tract should be carefully regulated.

The consideration of local treatment is important. Baking and physiotherapeutic measures which produce heat will often increase the pain if employed early in the course of the illness. As the pain and paresthesias diminish, light gentle massage to the affected parts should be employed every day and mild electrical treatments, either galvanic or faradic, should be used three or four times a week. It is highly important that the joints in the distribution of the paralysis be passively moved every day and that the tendons about them be lightly manipulated. If contractures have developed an effort should be made to overcome them by stretching, passive movement and by deep massage. If all of these are of no avail tenotomy may have to be done. Even after paralysis of all four extremities has persisted for six to twelve months a fair to perfect recovery is possible.

### Lead Multiple Neuritis

The multiple neuritis of lead is essentially a motor one and sensory symptoms, if present at all, are extremely mild. The ordinary signs of lead poisoning are usually present for some time before those of neuritis develop. The condition usually begins in the upper extremities and is practically always bilateral. The first sign of paralysis is in the extensors of the hand and forearm and gradually the entire extremity is involved. The supinator longus muscle usually escapes. Atrophy and reactions of degeneration occur but fibrillations do not. If the disease progresses the peroneal group of muscles is affected in the lower extremities.

### Postdiphtheritic Multiple Neuritis

The type of palsy occurring after diphtheria is usually limited to the uvula, palate and ciliary muscles. The symptoms are difficulty in swallowing, regurgitation of fluids through the nose and paralysis of accommodation. Some of the other cranial nerves may rarely be paralyzed. The paralysis may occur in the course of the disease or may be postponed for days, weeks or months. Paralysis of a part of an extremity may occur if the diphtheritic infection has taken place in that region.

If the polyneuritis of diphtheria becomes generalized the symptoms due to involvement of the nerves affected will appear. As a rule, pain is not a common symptom but the other signs such as loss of reflexes and of sensation, foot-drop and steppage gait occur. The gait may be ataxic. The outlook is good. Involvement of the cranial nerves, however, is a dangerous thing and sudden death may occur from heart failure or the patient may choke to death.

The *treatment* of diphtheritic multiple neuritis is the same as mentioned for other forms of multiple neuritis.

### Arsenical Multiple Neuritis

Arsenical multiple neuritis presents no outstanding features except that it is usually very painful. Certain skin manifestations such as pigmentation, exfoliating dermatitis, herpes and keratoses on the palms and soles of the feet may be seen.

The *treatment* does not vary from that of other forms of the disease. (See chapter 13)

### Diabetic Multiple Neuritis

The *symptoms* here may be due to involvement of the peripheral nerves or to changes in the cord.

The lower extremities are especially involved and the affection is frequently of the tabetic type. Alcohol sometimes plays a contributing role in this condition.

Other conditions may produce multiple neuritis such as carbon monoxide poisoning, beriberi, leprosy and so called pink disease or *erythredema polyneuritis*. It has also been called *acrodynia*. The latter condition is usually seen in children and is frequently accompanied by insomnia, restlessness and swelling and redness of the fingers and toes and possibly also trophic conditions, even gangrene.

### Polyneuronitis

*Definition.*—Infectious involvement of the entire neuron is called neuronitis. The *symptoms* resemble those seen in multiple neuritis but cranial nerve involvement, especially of the seventh nerve, is a common additional sign. Bulbar symptoms frequently are seen and may produce sudden death. Often the proximal muscles are more involved than the distal. Sensory disturbances may be slight or absent. Examination of the spinal fluid often shows an increased protein content without any increase in the number of cells (albumino-cytologic dissociation of Guillain and Barré). The condition usually runs a benign course. The treatment is symptomatic.

### Sciatica

Sciatica is more frequently seen in males. It frequently is observed after infectious diseases or may be due to chronic focal infection especially in the prostate. It may *follow exposure to cold*. It *may occur after* intragluteal medication. It may come on *after a heavy lifting or a marked muscular* exertion especially in people not used to such exertion. It may be due to herniation of the intervertebral disks. True sciatica is usually unilateral. If double sciatica exists it is *imperative to rule out the conditions* such as syphilis and tumor of the spinal cord. It may be an occupational disease due to pressure on the nerve due to prolonged sitting.

*Symptoms*.—The onset is usually gradual but in certain infectious cases and in those due to stretching of the nerve during physical exertion the signs may come on abruptly. *Pain begins as a rule in the* buttock and follows the course of the nerve down the back of the thigh, calf heel and to the foot. While the pain is usually constant it may be paroxysmal and like most pains is worse at night. Coughing sneezing jarring and motion aggravate the pain *which is usually sharp but may be dull*. The patient tries to prevent pain by keeping the extremity flexed at the ankle and the hip and if he is in bed he holds the extremity flexed at the knee and abducted. He is likely to stand on the healthy extremity the *gluteal fold is low on the affected side and a scoliosis is usually seen with the convexity* toward the diseased area. Anything which stretches the nerve such as bending forward to touch the floor with the fingers or testing for Lasègue's sign (which is done in the same manner as Kernig's sign) makes the patient cry out with pain. Tender points may exist along the *course of the nerve*. Paralysis and sensory loss are uncommon but the latter especially may occur in the distribution of the nerve. The knee jerk is not affected in fact due to the tenseness of the patient it may be slightly exaggerated. The Achilles reflex is diminished or lost. Muscular *atrophy and changes in electrical reactions* do not occur except in very rare cases. Trophic and vasomotor signs may be seen.

Most patients will recover although the condition may be very resistant to treatment and persist for months.

As far as the *differential diagnosis* is concerned a condition should be called sciatica only as a last resort. Careful investigation of the pelvis rectum and spine with particular search for evidence of *syphilis spinal cord tumors, protrusion of* the intervertebral disks focal infections, evidence of arthritis especially of the hip and sacro-iliac joint elimination of flat feet and of arterial disease should be gone into before the diagnosis of sciatica is made.

The most important element in the *treatment* is rest. *A combination of bromide and* salicylate will quiet the patient and relieve the pain. In view of the fact that the condition may be prolonged opium and its derivatives should not be used. Heat either dry or wet usually gives the patient considerable relief and diathermy over the nerve is sometimes of *considerable value*. *If the pain is very severe 5 to 10 cc of a 1 per cent solution of novocaine may be injected epidurally* in the sacral canal and followed in a few minutes by the injection of 50 cc of normal sterile saline. Direct injection into the nerve sheath of normal saline or alcohol and stretching of the nerve have been used but usually with poor results. The less stretching *and injection done the happier the patient*. In rare cases exposure of the nerve and freeing it of adhesions have benefited the patient.

### Peripheral Facial Paralysis (Bell's Palsy Prosoplegia)

This is probably the commonest type of peripheral neuritis. It is much more frequently seen in the spring and fall and is usually due to exposure *and chilling of the* face. A facial palsy may be seen in the course of any infectious disease in ear infection in tumors of the parotid tumors in the cerebellopontile angle syphilis in the cerebellopontile angle and direct trauma to the nerve. It is occasionally the result of *operations on the parotid or on the ear*. Tetanus especially when the wound of entrance is about the *face* may *produce*

facial paralysis. Facial diplegia is usually due to neurosyphilis at the base, to polyneuronitis and to encephalitis. Occasionally facial diplegia is seen in myasthenia gravis and *muscular dystrophy*. *The weakness of* the face which occurs in bulbar palsy is chiefly in the lower half. A lesion in the pons at the level of the seventh nucleus will produce facial paralysis of the peripheral type, but signs indicative of pontine rather than peripheral disease will be present.

*Symptoms.*—The symptoms are paralysis of the muscles on one side, which is flattened. The corner of the mouth droops and the face may seem drawn to the normal side. The wrinkles and folds normally present on the affected side will be smoothed out either in part or entirely; the eye cannot be closed and the palpebral fissure is wider than normal. Voluntary movement on the affected side is impaired and this may vary from slight weakness to total paralysis. *The patient has difficulty* in chewing because food has a tendency to collect between the gums and the cheek. He frequently drools at first and has slight difficulty in speaking. Because the blinking reflex is lost and there is a relaxation of the lower lid, tears often flow from the eye on the affected side. The loss of reflexes is due to involvement of the motor part of the arc. If the chorda tympani is involved there is a disturbance of taste on the side of the lesion on the anterior two thirds of the tongue. Occasionally herpes of the internal auditory meatus and the auricle with pain in these parts may be a part of the picture (syndrome of the geniculate ganglion). In this there is deep-seated pain in the ear and the mastoid region and occasionally lymphocytosis of the cerebrospinal *fluid*. Occasionally the eighth nerve is involved. Sensation is not affected in the ordinary type of Bell's palsy. In ten days to two weeks after the onset of paralysis, changes in the electrical reactions may occur. These changes may vary *from slight reduction* in contractility to faradism to complete reactions of *degeneration*.

*Diagnosis.*—The most important consideration in the diagnosis of Bell's palsy is to differentiate it from a paralysis of the face of central origin which is usually a part of the picture of hemiplegia, in which condition only the lower part of the face is involved. The tongue deviates to the paralyzed side. Electrical reactions are not affected. The *muscles may move well during emotionalism*. Furthermore in hemiplegia the rest of the same side of the body will be affected.

In bilateral facial paralysis, syphilis, polyneuronitis and encephalitis should be considered from a diagnostic standpoint. If syphilis is to blame, involvement of the eighth nerve may also be seen.

*Prognosis.*—The prognosis in facial paralysis naturally depends upon the cause. If it is the ordinary type due to exposure, the chances for a complete recovery are good. The most valuable aid in prognosis is the reaction of the nerve to electricity two weeks after the onset. The milder the changes to faradism or galvanism, the better is the prognosis. Mild cases will do well in three to six weeks, whereas severe cases may last from three months to one year. If the nerve has been cut during an operation or if involved by a parotid tumor, the outlook is not good. Many patients will recover with contractures, especially those who are treated too vigorously by local measures. Associated movements may be seen on the side of the face which has recovered partially from a Bell's palsy; for example, when a patient winks the eye on the affected side the angle of the mouth draws up and *vice versa*. The reason for this is probably misdirection of the regenerating fibers. Years after a Bell palsy has cleared up facial spasm may be noted on the affected side.

*Treatment.*—The eye should be protected with a patch and washed out frequently with warm boric acid. Small to moderate doses *of sodium salicylate and sodium iodide* should be given and continued for two or four weeks. If there is much drooping on the weakened side this may be strapped up with adhesive. Ten days to two weeks after the onset of paralysis electrical treatment should be initiated on alternate days. If faradism produces a response, that type of electricity should be used; if it does not, galvanism should be employed. On the alternate days mild gentle massage will aid in recovery. As soon as voluntary movement begins to return the number of local treat-

ments should be reduced and when further movement has been established all local treatment should be stopped Treatment should be persisted in for at least six months after the onset, and even after six months of paralysis some cases may make a good recovery Anastomosis of the central end of the hypoglossus or of the spinal accessory with the distal stump of the facial has been tried Neither type of anastomosis is as a rule successful

### Hemifacial Spasm

This condition may involve either the entire facial nerve or one of its branches The movements are painless and resemble those produced by electrical stimulation of the nerve It occasionally occurs without any detectable cause but may be symptom of pressure on the nerve as for example by a tumor in the angle It has been known to follow years after an ordinary Bell palsy

*Treatment* should depend on the cause if none is discoverable psychotherapeutic procedures injection of the nerve with alcohol or partial section of it may be tried but the results are usually disappointing

### Progressive Hemifacial Atrophy

This is a condition which usually begins before puberty is more common in females and more frequently involves the left side of the face The atrophy is first noted in the skin usually at the external angle of the orbit or at the angle of the mouth, and then gradually spreads until it involves the entire side of the face The skin becomes thin fat disappears and later on the underlying muscles and bones become atrophic but actual paralysis and reactions of degeneration do not occur The corresponding side of the tongue even of the soft palate may become atrophic Changes in the hair and of the sweat secretion on the side of the face involved may be found There is neither loss of sensation nor disturbance of taste The cause of this condition is unknown When it occurs in syringomyelia the typical dissociation loss of sensation will be found The condition has been attributed to trauma and may have an important medico legal aspect

### Hemifacial Hypertrophy

Facial hemihypertrophy is an extremely rare condition in which the soft tissue and the bones on one side of the face hypertrophy This may occasionally be found associated with enlargement of one entire side of the body

## NEURALGIA

*General Discussion* —Neuralgia is usually a symptom and not a disease It consists in paroxysmal attacks of pain in the course of a sensory nerve If the neuralgic condition is hysterical in origin it would properly be called psychalgia The most common form of neuralgia is trigeminal (tic douloureux or trifacial neuralgia)

### Trigeminal Neuralgia

Trifacial neuralgia (tic douloureux) is most frequently seen in patients in middle or advanced life Its cause is not known The pain is in the distribution of the fifth nerve If confronted with a patient suffering from pain in the face either in one or all of the branches of the fifth nerve, it is important to rule out conditions which may either by pressure or reflexly cause pain in the area of the trigeminal nerve Tumors in the angle tumors of the Gasserian ganglion diseases of the teeth or the sinuses basilar syphilis and general toxemias or infectious especially malaria, should be considered

*Symptoms* —The pain will obviously be in the distribution of the branch involved but it may spread to the entire supply of the trigeminal nerve Occasionally the pain is bilateral The pain occurs suddenly, is excruciating burning and violent It may last a few seconds or minutes and occurs paroxysmally After a number of attacks in the course of days the pain may subside and disappear for weeks or months During an attack the patient holds the face and head in a set manner, because opening the mouth talking chewing or swallowing may bring on an attack of pain Washing the face or exposure to cold may also bring on an attack Flushing of the skin, and an abnormal flow of tears or saliva and local sweating may be seen Tic like movements of the face smacking of the lips and movements of the jaw may occur The tender points or *trigger zones* so called because irritation of them may bring on an attack, are found along the course of the nerve The symptoms are usually more marked in the daytime

*Diagnosis* —The diagnosis is made chiefly from the conditions mentioned in the fore-

going remarks The presence of sensory findings will rule out organic affections of the ganglion and of the roots of the nerve The pain of *Sluder s neuralgia* is not limited to the fifth nerve, and has a tendency to radiate to the shoulder the importance and frequency of this has been greatly over estimated In *glossopharyngeal neuralgia* the pain radiates from the pharynx to the side of the neck and to the ear The tonsil may act as a trigger zone thus swallowing may bring on an attack

*Treatment* — The medical treatment of trigeminal neuralgia is usually without value Heat especially diathermy may produce considerable relief

The patient usually has to submit either to injection of the branches of the nerves or ganglion with absolute alcohol or to avulsion of the sensory root The injection with alcohol is also an important diagnostic procedure in distinguishing between trigeminal neuralgia and psychalgia The mortality following avulsion is less than 1 per cent and it results in few postoperative complications of which facial paralysis trophic disorders and deafness are the commonest Loss of sensation of course occurs in the distribution of the fifth nerve The operation is usually curative Recently Sjoqvist has advocated intramedullary tractotomy for relief of the intractable pain in the face

### Glossopharyngeal Neuralgia

The paroxysmal pain of this condition is similar to that seen in *tic douloureux* except for the distribution The pain radiates from the pharynx to the side of the neck and to the ear The pharynx and tonsil often act as a trigger zone and as a result swallowing frequently causes a paroxysm of pain Yawning may bring on a paroxysm The cause is unknown *The differential diagnosis* is to be made especially from trigeminal neuralgia Injection of the fifth nerve with alcohol will not produce a loss of pain if the condition is due to glossopharyngeal neuralgia Alcohol injection of the glossopharyngeal is hazardous because of the danger of injecting the vagus Avulsion of the root is curative and should be done intracranially The other types of neuralgia such as occipital brachial, intercostal and that of the lumbosacral regions usually have an organic basis behind them

### Coccygodynia

Neuralgia of the coccygeal nerves or coccygodynia in which the pain is referred *to the tip of the coccyx, which is tender,* is usually hysterical It comes on after trauma or childbirth and is aggravated by walking or sitting The proper treatment is psychotherapy Removal of the coccyx does not cure the condition unless it does so by its psychotherapeutic element

## LESIONS OF THE PERIPHERAL NERVES OF THE EXTREMITIES

### Ulnar Nerve

The ulnar nerve supplies the two inner heads of the flexor profundus digitorum the adductors of the thumb the inner head of the flexor brevis pollicis and the muscles of the hypothenar eminence the inner two lumbricales and all of the interossei The sensory part of the nerve supplies the palmar and dorsal surface of the little and the inner half of the ring finger and the inner side of the palm and back of the hand to a short distance above the wrist The nerve may be injured by direct trauma or by pressure such as for example pressure exerted on the deep *branch of the ulnar in* the palm or the pressure of leaning the elbows on a desk or chair The nerve may be *involved in a lesion of the brachial plexus* dislocation of a shoulder or elbow by pressure of splints fractures in or about the elbow, which later give rise to excessive callus formation The latter condition may cause an ulnar paralysis months or years after the primary injury Leprosy has a *special tendency* to involve the ulnar nerve If the injury is high flexion of the hand is weak and it is turned toward the radial side Extension of the distal phalanges and flexion of the proximal ones are impaired or lost so that claw hand (*main en griffe*) is formed due to unopposed action of the radial nerve Adduction of the fingers is impaired adduction of the thumb is *lost* Froment s sign is present This consists of a

flexion of the thumb when the patient tries to hold a piece of paper between his thumb and index finger, while an attempt is made to pull the paper away. The muscles supplied by the nerve waste. This is especially noticeable in the hypothenar eminence in the palm and the interosseous spaces which become hollowed out. Sensory loss corresponds to the anatomic distribution of the nerve and in mild cases is usually greater for touch than for any other form of sensation. Pain and paresthetic phenomena may be severe and vasomotor and trophic changes may cause distressing complications.

## SCALENUS COMPRESSION SYNDROME (SEE CHAPTER 24)

## THE MEDIAN NERVE

*The median nerve supplies the pronator* quadratus and the pronator radii teres the flexor carpi radialis the flexor sublimis the *two outer heads of the flexor profundus* digitorum the abductor and opponens of the thumb the flexor longus and part of the *flexor brevis pollicis and the two outer* lumbricales.

The sensory part of the nerve supplies the *outer part of the palm from the middle of* the ring finger to the thumb. On the dorsal aspect of the hand the nerve supplies the last *two phalanges of the index middle and* radial half of the ring fingers. The median is especially rich in trophic and vasomotor fibers. *The nerve may be affected anywhere* along its course for example by dislocation of the shoulder by bullet or stab wounds and it *may be involved as a part of a general* multiple neuritis. Depending on the level at which the nerve is involved the extent of the paralysis varies. Ordinarily implication of the nerve produces weakness of flexion at the wrist and flexion at the distal phalanges of the middle and index fingers especially the latter are greatly disturbed. The thumb is adducted and extended and the terminal phalanx of the thumb cannot be flexed. The thumb cannot be brought to touch the tips of the fingers. The thenar eminence and the pulps of the middle and index fingers and thumb become atrophic. Sensory loss is as a rule as great as the distribution of the nerve. Involvement of the median nerve usually produces a severe amount of burning pain which was designated by Mitchell as *causalgia*. It is a burning boring intractable pain which makes life unbearable. The nails in the distribution of the nerve become dry brittle and furrowed and the skin tense and glossy.

## MUSCULOSPIRAL NERVE (RADIAL NERVE)

This nerve supplies the triceps the anconeus, the brachioradialis, the extensors of the forearm and the long extensors of the *fingers and thumb*. The cutaneous distribution of the nerve varies. The posterior aspects of the hand not supplied by the median and *ulnar are innervated by the radial*. This is approximately the radial half of the dorsal aspect of the hand dorsal aspect of the *thumb of the index finger to the first* phalanx and the radial half of the middle finger to the first phalanx. The musculo*spiral nerve is frequently injured especially* by pressure in the axilla from a crutch during deep sleep especially a drunken one, *in which the weight of the head rests on the* humerus and presses against the nerve and by fracture of the humerus. It can also of *course be injured by bullet wounds or stab* wounds. The commonest cause is pressure on the nerve by drunken sleep the so-called Saturday night paralysis. Lead produces a double musculospiral paralysis *in which the supinator longus muscles are spared*. The paralysis which results from musculospiral palsy will depend upon the height of the injury to the nerve for example, if it is injured in the axilla there is paralysis in the entire distribution of the nerve including the triceps. The usual location of the involvement which is in the arm spares the triceps. There is paralysis of the extensors of the hand thumb and fingers the proximal phalanges of the latter being involved. The rest of the finger extension is done by the non paralyzed interosseous muscles. The forearm is pronated the wrist drops and the thumb is adducted flexed and opposed. The hand grip is weak if the patient attempts to grasp an object with the wrist dropped but if the hand is supinated

going remarks The presence of sensory findings will rule out organic affections of the ganglion and of the roots of the nerve The pain of *Sluder's neuralgia* is not limited to the fifth nerve and has a tendency to radiate to the shoulder, the importance and frequency of this has been greatly overestimated *In glossopharyngeal neuralgia* the pain radiates from the pharynx to the side of the neck and to the ear The tonsil may act as a trigger zone thus swallowing may bring on an attack

*Treatment* —The medical treatment of trigeminal neuralgia is usually without value Heat especially diathermy, may produce considerable relief

The patient usually has to submit either to injection of the branches of the nerves or ganglion with absolute alcohol or to avulsion of the sensory root The injection with alcohol is also an important diagnostic procedure in distinguishing between trigeminal neuralgia and psychalgia The mortality following avulsion is less than 1 per cent and it results in few postoperative complications of which facial paralysis trophic disorders and deafness are the commonest Loss of sensation, of course occurs in the distribution of the fifth nerve The operation is usually curative Recently Sjoqvist has advocated intramedullary tractotomy for relief of the intractable pain in the face

### Glossopharyngeal Neuralgia

The paroxysmal pain of this condition is similar to that seen in tic douloureux except for the distribution The pain radiates from the pharynx to the side of the neck and to the ear The pharynx and tonsil often act as a trigger zone and as a result swallowing frequently causes a paroxysm of pain Yawning may bring on a paroxysm The cause is unknown The differential diagnosis is to be made especially from trigeminal neuralgia Injection of the fifth nerve with alcohol will not produce a loss of pain if the condition is due to glossopharyngeal neuralgia Alcohol injection of the glossopharyngeal is hazardous because of the danger of injecting the vagus Avulsion of the root is curative and should be done intracranially The other types of neuralgia such as occipital brachial intercostal and that of the lumbosacral regions usually have an organic basis behind them

### Coccygodynia

Neuralgia of the coccygeal nerves or coccygodynia in which the pain is referred to the tip of the coccyx, which is tender, is usually hysterical It comes on after trauma or childbirth and is aggravated by walking or sitting The proper treatment is psychotherapy Removal of the coccyx does not cure the condition unless it does so by its psychotherapeutic element

## LESIONS OF THE PERIPHERAL NERVES OF THE EXTREMITIES

### Ulnar Nerve

The ulnar nerve supplies the two inner heads of the flexor profundus digitorum, the adductors of the thumb the inner head of the flexor brevis pollicis and the muscles of the hypothenar eminence the inner two lumbricales and all of the interossei The sensory part of the nerve supplies the palmar and dorsal surface of the little and the inner half of the ring finger and the inner side of the palm and back of the hand to a short distance above the wrist The nerve may be injured by direct trauma or by pressure such as for example pressure exerted on the deep branch of the ulnar in the palm or the pressure of leaning the elbows on a desk or chair The nerve may be involved in a lesion of the brachial plexus dislocation of a shoulder or elbow by pressure of splints fractures in or about the elbow which later give rise to excessive callus formation The latter condition may cause an ulnar paralysis months or years after the primary injury Leprosy has a special tendency to involve the ulnar nerve If the injury is high flexion of the hand is weak and it is turned toward the radial side Extension of the distal phalanges and flexion of the proximal ones are impaired or lost so that claw hand (*main en griffe*) is formed due to unopposed action of the radial nerve Adduction of the fingers is impaired adduction of the thumb is lost Froment s sign is present This consists of a

hypertrophy may be seen. The wasted fibers are replaced by fibrous tissue and fat, producing myosclerosis. Pseudohypertrophy occurs in a form of the disease, especially implicating the deltoids and muscles of the calf. The muscles apparently enlarged have a hard inelastic feel. The age of onset is usually before ten years, but it may be delayed as late as twenty five years and cases have been reported even up to forty years of age. The amount of creatinine excreted daily is low. A diminished tolerance for creatine exists which bears some relation to the severity of the symptoms.

*Symptoms*.—The muscles involved are those of the trunk, the shoulder girdles, pelvic girdles, arms and thighs. The muscles below the elbows and below the knees may be affected early, but this is contrary to the rule and serves as one of the chief differential points between muscular dystrophy and the atrophies of the spinal origin. The face, while implicated in many cases, is not as a rule first involved. Due to involvement of the muscles of the hip and of the spine, the gait is of the so-called duck or waddling type and resembles, to a degree, that seen in double congenital dislocation of the hips. Weakness of the muscles of the spine causes distinct lordosis and great difficulty when the patient attempts to arise from a sitting position on the floor. The manner in which a patient with muscular dystrophy arises from the floor (he climbs up himself) is one of the most characteristic things in the disease, but may be seen in any patient who has weakness of the back and gluteal muscles from other causes. The involvement of the muscles of the shoulder girdles and the arms produces loose shoulders and winged scapulæ. As the muscles waste, their movements become weaker and gradually disappear. The same thing holds good for the deep reflexes. Sensation is normal and fibrillations are usually not seen. While the electrical reactions diminish and finally disappear, there are no reactions of degeneration. Some of the muscles may appear unusually large. This is due to replacement of the muscle with fat or connective tissue. In some cases actual hypertrophy of the muscle occurs. Such a muscle is harder than usual and yet may be weak to the point of paralysis. If the face is involved the so-called myopathic facies is seen. Wrinkles are absent, the folds are flattened out, tapir mouth ensues and the palpebral fissures are widened. All these symptoms are due to weakness in the distribution of the seventh nerves. The smile is a transverse one. The muscles are involved bilaterally and more or less symmetrically. The heart muscle has been involved in some cases. Contractures and ankylosis frequently occur, especially in patients who have very little attention paid to them in the line of physiotherapy. Some of the cases of dystrophy become freaks in the side shows of circuses. It is rare to have involvement of the tongue, ocular and jaw muscles.

The course of the disease is gradually progressive. Victims suffering from it are quite likely to be carried off by acute infections, but many live twenty to forty years after the onset. In some the disease progresses so very slowly that it appears to be arrested.

If it be borne in mind that the disease occurs early in life, chiefly in males, that the proximal segments of the limbs are affected, power, reflexes and electrical reactions gradually disappear, that there are no changes in sensation and that fibrillary tremors are unknown, there should be no difficulty in the diagnosis. Muscle biopsy is sometimes helpful.

There is no specific *treatment*. Massage and passive movements to the joints may prevent the occurrence of deformities. The use of glycine or glutamic acid has been disappointing as has been the results of vitamin E therapy.

## NEUROLOGY IN RELATION TO WAR

In addition to being subject to the same neurologic diseases as may afflict the civilian in peace time, the soldier in a global mechanized war is exposed to many hazardous conditions which tend to increase the incidence of neurologic disorders.

There are few if any neurologic diseases peculiar to war alone, but certain conditions occur much more frequently under war conditions than in civilian life and are worthy of brief mention.

the grasp will be good The sensory loss is not nearly so extensive as the distribution of the nerve, and, in many cases practically no sensory loss occurs

### Long Thoracic Nerve

This nerve supplies the serratus magnus It may be paralyzed from injury, carrying heavy weights on the shoulder and from inflammatory reactions The inferior angle of the scapula stands away from the chest and, on elevating the arm, the scapula becomes winged Weakness is encountered in raising the arm above the horizontal plane The lifting ability of the patient is diminished Pain is not usually present and the prognosis for recovery is fair

### Circumflex Nerve

This nerve supplies the deltoid and teres minor The sensory branch of the nerve supplies an oval space over the deltoid muscle If the nerve is completely involved the shoulder joint is relaxed the deltoid atrophic and the arm cannot be abducted Changes in electrical reactions occur Outward rotation of the arm is interfered with Pain is frequently severe and a loss of sensation occurs in the distribution of the nerve In arriving at a diagnosis, local conditions of the shoulder must be considered and ruled out

### External Popliteal

This is the external division of the sciatic and supplies the antero-external muscles of the leg the extensor longus digitorum the extensor proprius pollicis the tibialis anticus the peroneus brevis and the peroneus longus It innervates the skin on the dorsal surface of the first metatarsal and big toe, the antero-external surface of the leg and the dorsum of the foot including the dorsum of the great toe first second and third toes up to the second phalanges This nerve is frequently involved by direct injury especially as it winds around the head of the fibula, where it is susceptible to the pressure of a cast, to direct blows and to disease involving the upper part of the fibula It may be paralyzed as the result of occupation when the nerve is frequently squeezed, for example, in hardwood floor polishers and people who work in gardens and frequently bend the knees Crossing the legs for long periods especially in thin individuals also causes paralysis Lead involves the nerve bilaterally It is also occasionally injured in the pelvis during difficult labors Involvement of the nerve produces paralysis of the extensors of the foot and of the extensors of the proximal phalanges of the toes and impairment of eversion Foot drop, pes equinovarus and occasionally flat foot result Steppage gait on the affected side appears Contractures due to unopposed muscles may set in Pain, trophic and vasomotor changes are unusual and the cutaneous sensory loss is less than the supply of the nerve itself

*Treatment* —This will depend in a large measure upon the cause If there is evidence that the nerve has been directly injured by bullet wounds stab wounds or fracture or by pressure of the fragments of bone it should be investigated surgically as soon as possible although many patients with peripheral nerve injury complicated by complete paralysis of the nerve may make a total recovery without operation Some choose to wait six to twelve weeks before surgical interference If the nerve has been involved by pressure or infections or toxic cause surgical intervention is not indicated A splint or appliance should be made to support the muscles paralyzed Massage should be given daily or at least three times a week and faradism or galvanism applied to the affected nerve three times a week The outlook in pressure cases is usually good although the individual nerve may take from three to six months to recover Various orthopedic operations may produce more useful extremities if the nerve paralysis does not recover

## THE MYOPATHIES

### Progressive Muscular Dystrophy

This disease is strictly limited to the muscles The causes other than familial tendency to the disease are not known The nervous system, both central and peripheral is intact The muscle fibers show atrophy though occasionally a true

hypertrophy may be seen. The wasted fibers are replaced by fibrous tissue and fat, producing myosclerosis. Pseudohypertrophy occurs in a form of the disease, especially implicating the deltoids and muscles of the calf. The muscles apparently enlarged have a hard noneiastic feel. The age of onset is usually before ten years but it may be delayed as late as twenty five years, and cases have been reported even up to forty years of age. The amount of creatinine excreted daily is low, a diminished tolerance for creatine exists which bears some relation to the severity of the symptoms.

*Symptoms*.—The muscles involved are those of the trunk, the shoulder girdles, pelvic girdles, arms and thighs. The muscles below the elbows and below the knees may be affected early, but this is contrary to the rule and serves as one of the chief differential points between muscular dystrophy and the atrophies of the spinal origin. The face, while implicated in many cases, is not as a rule first involved. Due to involvement of the muscles of the hip and of the spine the gait is of the so-called duck or waddling type and resembles to a degree that seen in *double congenital dislocation of the hips*. Weakness of the muscles of the spine causes distinct lordosis and great difficulty when the patient attempts to arise from a sitting position on the floor. The manner in which a patient with muscular dystrophy arises from the floor (he climbs up himself) is one of the most characteristic things in the disease, but may be seen in any patient who has weakness of the back and gluteal muscles *from other causes*. *The involvement of the* muscles of the shoulder girdles and the arms produces loose shoulders and winged scapulæ. As the muscles waste their movements become weaker and gradually *disappear*. The same thing holds good for the deep reflexes. Sensation is normal and fibrillations are usually not seen. While the electrical reactions diminish and finally disappear there are no reactions of degeneration. Some of the muscles may appear unusually large. This is due to replacement of the muscle with fat or connective tissue. In some cases actual hypertrophy of the muscle occurs. Such a muscle is harder than usual and yet may be weak to the point of paralysis. If the face is involved the so-called myopathic facies is seen. Wrinkles are absent, the folds are flattened out, tapir mouth ensues and the palpebral fissures are widened. All these symptoms are due to weakness in the distribution of the seventh nerves. The smile is a transverse one. The muscles are involved bilaterally and more or less symmetrically. The heart muscle has been involved in some cases. Contractures and ankylosis frequently occur, especially in *patients* who have very little attention paid to them in the line of physiotherapy. Some of the cases of dystrophy become freaks in the side shows of circuses. It is rare to have involvement of the tongue, ocular and jaw muscles.

The course of the disease is gradually progressive, victims suffering from it are quite likely to be carried off by acute infections, but many live twenty to forty years after the onset. In some the disease progresses so very slowly that it appears to be arrested.

*If it be borne in mind that the disease* occurs early in life, chiefly in males, that the proximal segments of the limbs are affected, *power, reflexes and electrical reactions* gradually disappear, that there are no changes in sensation and that fibrillary tremors are unknown, there should be no difficulty in the diagnosis. Muscle biopsy is sometimes helpful.

There is no specific *treatment*. Massage and passive movements to the joints may prevent the occurrence of deformities. The use of glycine or glutamic acid has been disappointing as has been the results of vitamin E therapy.

## NEUROLOGY IN RELATION TO WAR

In addition to being subject to the same neurologic diseases as may afflict the civilian in peace time, the soldier in a global mechanized war is exposed to many hazardous conditions which tend to increase the incidence of neurologic disorders.

There are few if any neurologic diseases peculiar to war alone, but certain conditions *occur much more frequently* under war conditions than in civilian life and are worthy of brief mention.

Clinical and experimental data have shown that high explosive blasts may cause injury to the central nervous system without evidence of any external trauma. Lesions in the nervous system, particularly hemorrhages, were found at autopsy in soldiers dying after exposure to such blasts, while some men who recovered exhibited residual neurologic symptoms such as hemiplegia, paraplegia, pupillary and sphincter disturbances. In one group of 74 soldiers, 67 showed unmistakable signs of localized organic lesions of the central nervous system. Such signs often tended to be transient, having for the most part disappeared before a second examination a week later. Subdural hematoma and effusion have been reported as complications of high explosive blast injuries, on both land and in water. It is of interest that clinical neurologic abnormalities were not detected in approximately 80 per cent of the cases and the diagnosis depended mainly on psychiatric findings in the form of retardation in intellectual activity, and personality and mood disturbances. Some of the cases were erroneously diagnosed at first as war neurosis, traumatic neurosis or psychoneurosis. While we do not believe that all neuroses of war are due to structural disturbances of the nervous system, evidence such as the above suggests that many war neuro-psychiatric conditions blandly assumed to be due to anxiety, fright, "combat fatigue" and other emotional causes might likewise have a structural background if it were carefully sought after.

Another type of neurologic disturbance frequently encountered in war but rather rare in civilian life is the so-called reflex paralysis. In this condition rigidity and paralysis leading to immobilization of a limb and often accompanied by pronounced vasomotor disturbances occurred following an injury or wound in a remote part of the body. The cause of these reflex paralyses is still uncertain. Some consider them an hysterical manifestation, others as the result of immobilization or inactivity, while still others subscribe to the concept that disturbed sympathetic innervation is responsible.

### Causalgia

Causalgia, first described by Weir Mitchell in the Civil War, is likewise not infrequent following war injuries. In this condition following gunshot or other wounds involving certain peripheral nerves, especially the median and tibial, there occurs a characteristic paroxysmal type of pain in the injured member accompanied by severe trophic and vasomotor changes in the painful area. Jarring, air currents and emotional upsets may initiate the pain, while relief is afforded by placing the hand or foot in water. Some ascribe the condition to a disturbance of sympathetic regulating fibers, while Lewis suggests that the pain arises from irritation in the skin or peripheral nerve of nocifensor fibers which are a division of the posterior root system. Relief may be obtained in the early stages by local infiltration with procaine, paravertebral injections or sympathetic ganglionectomy. In the later stages these measures are of little avail and the pain persists even after rhizotomy and chordotomy.

### Phantom Limb

Following amputation of part of an extremity, especially an upper, the patient will frequently complain of discomfort, pain, itching and other disagreeable sensations in the part which has been lost. The symptoms are often extremely distressing; their cause is not absolutely determined, but it is likely that the brain misinterprets sensations arising from stimulation of the remaining stumps of the nerves as originating in the distal parts now lost. Treatment of this condition often is difficult. Occasionally resection of the nerve in the stump and sympathectomy will be helpful, but often more radical procedures such as excision of the parietal sensory cortex are necessary.
